Hemicyanine (styryl) dyes can be prepared by reaction of 4-dialkylaminobenzaldehydes or the vinylogous cinnamaldehydes with quaternary N heterocycles that have a methyl or methylene group capable of undergoing reaction. For example, 4-dimethylaminocinnamaldehyde gives Pyridine 1 with quaternary 2-methylpyridine and Pyridine 2 with quaternary 4-methylpyridine, respectively (see Table 7) [72].

In the same way, Styryl 6 is obtained from 1,3,3-trimethyl-2-methyleneindoline, Styryl 8 from quaternary 2-methylbenzothiazole, and Styryl 11 (all Lambda Physik) from quaternary lepidin, respectively (see Table 7) [72].

Neutrocyanine dyes with aromatic [73] (**20**) or heterocyclic (**21**) [74] terminal groups are also suitable for producing laser radiation.

4-Dicyanomethylene-2-methyl-6-(3-ethyl-2-benzoxazolinylidenpropylene)-4*H*-pyran

Infrared Laser Dyes. According to the electron gas model [75] an increased number of conjugated double bounds should lead to a bathochromic shift of cyanine dyes. This concept was used for the synthesis of IR laser dyes by DREXHAGE et al. [82], [106], [107], [108], [109]. Laser action of dye molecules in the IR region is difficult to achieve. The compounds with a $S_0 \rightarrow S_1$ transition in the IR region show very small fluorescence quantum yields ($< 10^{-4}$) and generally a poor photostability. In [110] a review of IR laser dyes is given. The dye S 501 in *o*-dichlorobenzene, excited by picosecond pulses reaches the longest dye laser wavelength (tuning range between 1700 and 2000 nm). Remarkably, this dye solution could be used for many hours without a decrease in laser efficiency.

22

2.7. Oxazine Dyes

Replacement of the −CH= group in xanthene dyes with nitrogen leads to the oxazine dyes. According to the electron gas model of methine dyes (H. KUHN) [75] replacement of the central methine group by a group with greater electron affinity should produce a marked bathochromic shift. This is in fact the case. The tuning range of the oxazine dyes is 640 – 900 nm (for preparation of these dyes see → Azine Dyes). Two

Table 8. Tuning ranges of some oxazine laser dyes

Dye	CAS registry number	Structure	Tuning range, nm	
			XeCl Excimer	cw Argon
Oxazine 1	[*24796-94-9*]		692 – 768	695 – 800 [a]
Oxazine 4	[*60786-96-1*]		665 – 718	
Cresyl Violet 670	[*41830-80-2*]		643 – 688	650 – 695
Nile Blue A	[*53340-16-2*]		688 – 747	690 – 780
Oxazine 750	[*85256-40-2*]			790 – 900 [a]
Phenoxazone 9	[*7385-67-3*]			560 – 700 [b]

[a] With cw krypton laser. [b] With nitrogen laser (in ethanol).

efficient diaminophenoxazine dyes are Oxazine 1 and Oxazine 4 (Kodak, Lambda Physik) (see Table 8) [76].

The fluorescent quantum yield of Oxazine 4 increases from 63 to 89 % in *O*-deuterated alcohols. The factor responsible for this effect is apparently the reduced radiationless deactivation by N–H vibration because of a partial H – D exchange. Oxazine 1 possesses no NH group and does not show this effect. In the latter case, however, the fluorescent quantum yield increases with decreasing temperature, due to hindered rotation of the amino group [77].

Cresyl Violet 670 and Nile Blue A (Kodak, Lambda Physik) are examples of diaminobenzophenoxazine dyes (Table 8) [76]. An increase in laser performance is observed by addition of Rhodamine 6 G to a solution of Cresyl Violet 670. Energy transfer occurs because the fluorescence band of Rhodamine 6 G overlaps the absorption band of Cresyl Violet [78]. The laser beam with longest wavelength is obtained with the ring-closed dye Oxazine 750 (see Table 8) [79].

Nile Blue A phenoxazone (Phenoxazon 9) displays pronounced solvatochromism. On stimulation with a nitrogen laser, the tuning range in ether is 580 – 631 nm and in hexafluoroisopropanol 690 – 743 nm. By mixing solvents, the wavelength range stretches from 580 to 743 nm without interruption [80].

1. Introduction

A laser is a device that generates coherent electromagnetic radiation in the infrared, visible, or ultraviolet region of the spectrum. The electromagnetic radiation generated by a laser differs from that of conventional sources in several respects:

1) Laser radiation can be extremely monochromatic; i.e., it can be described as having nearly a single frequency.
2) Laser radiation can be extremely directional.
3) Laser radiation can be extremely coherent both spatially and temporally; i.e., interference effects may be observed between portions of the output both spatially and temporally separated.
4) Laser radiation exhibits the statistical properties of an amplitude-stabilized oscillator rather than those of narrow-band Gaussian noise.

A typical laser may exhibit all of these properties to varying degrees. Laser radiation, regardless of frequency, is generally referred to as laser light.

Lasers are light amplifiers that operate using the principle of *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation (laser). The addition of sufficient correctly phased feedback around an optical or electronic amplifier will convert it into an oscillator. Although the vast majority of lasers are oscillators, laser amplifiers and oscillator-driven amplifier chain systems are not uncommon.

Stimulated emission of radiation may be described as follows. Atoms, ions, or molecules that have absorbed energy (been excited) can release their energy either radiatively or nonradiatively. Radiative decay may occur by the usually observed spontaneous emission or, alternatively, by stimulated emission. In spontaneous emission, light is emitted with random phase and direction and a frequency characterized by a line shape function. If light is incident on the excited species, they may be stimulated to emit their energy as additional light with the same frequency, phase, polarization, and direction as the incident light. The incident light appears amplified. This process is the converse of stimulated absorption in which light is attenuated. Whether stimulated emission or stimulated absorption predominates is determined by the ratio of the excited to the unexcited species. When the excited species out-

10.1002/14356007.a15_165

number the unexcited species, an inversion is said to exist and net amplification occurs.

Feedback in electromagnetic systems in which the physical size of the components is large compared to a wavelength is provided by resonant structures. These are usually some form of reflective box or cavity. Due to the very short wavelength of coherent light, which renders it highly directional, only two opposing sides of the box are necessary. These reflective sides of the box (mirrors) provide the feedback which allows the amplifier to oscillate.

Finally, all that is needed to complete a useful device is a means of coupling out some of the light circulating within the oscillator. The most common method is to make one mirror partially reflecting. The portion of the light not reflected is transmitted out of the cavity. Other techniques include shaping the mirrors so that the non-perfect directionality of the light allows part of it to bypass the mirror. For lasers that have a pulsed rather than a continuous-wave (cw) output, a switch can be inserted into the cavity which allows the light to bypass the mirrors when it is actuated.

The laser can trace its historical origins to masers, devices that operate on the same principle in the microwave portion of the electromagnetic spectrum. The first maser was operated by C. H. Townes, J. P. Gordon, and H. Zeiger at Columbia University. A device was built in the Soviet Union shortly thereafter by N. G. Basov and A. M. Prokhorov. These groups shared the 1964 Nobel Prize in Physics for their work. In 1958, A. L. Schawlow and C. H. Townes published a landmark paper which extended the theory of masers to the visible spectrum. Although not published at the same time, similar work was done by the then Columbia University graduate student Gordon Gould. This work was the basis for awarding the fundamental laser patent, after much litigation, to Gould's company, Patlex. Theodore H. Maiman demonstrated the first successful laser, a flashlamp-pumped ruby device operating at 694 nm, in 1960 at the Hughes Research Laboratories. In the same year, Ali Javan at the Bell Telephone Laboratories demonstrated the first gas laser in an electrically excited mixture of helium and neon at 1.15 μm. In 1961 the ubiquitous 633-nm helium – neon laser was demonstrated. Subsequent to these early developments, a plethora of published accounts of laser action in a wide variety of materials appeared and the field of laser research blossomed.

Today laser performance spans an enormous range. Powers range from microwatts to tens of kilowatts (cw), and pulsed terawatts (10^{12} W). Lasers operate from the microwave portion of the spectrum to the soft X-ray region. Laser pulse widths range from a few femtoseconds (10^{-15} s) to continuous wave. Bandwidths as low as 1 kHz have been measured. Lasers range from miniature semiconductor devices to the enormous machines required for inertial-confinement fusion.

2. Physical Principles

The physical principles of laser operation are covered in detail in [1]. These principles are summarized in this chapter.

2.1. Interaction Between Electromagnetic Radiation and Matter; Amplification of Light

Consider the atomic system shown in Figure 1A. Atomic levels 1 and 2 are separated by an energy corresponding to $h\nu$, where h is Planck's constant and ν is the resonant frequency. Level 1 is assumed to be the ground state of the atom. The other levels are minimally populated thermally. The decay rate of level 3 to level 2 is assumed to be faster than that of level 2 to level 1. A photon of frequency ν can be absorbed by the system, inducing a transition from level 1 to level 2. Level 2 may then spontaneously emit a photon of frequency ν. If the atom has been excited to level 2, an induced transition of the atom from level 2 to level 1 may occur. In this case, the transition energy ($h\nu$) is added to the stimulating light with the same frequency, direction, and polarization.

Under normal circumstances, levels 1, 2, and 3 are thermally populated according to the Boltzmann distribution:

$$n_2/n_1 = \exp(-h\nu/kT)$$

where k is the Boltzmann constant, T is the temperature, and n_1, n_2 represent the number of

atoms in levels 1 and 2, respectively. A similar relation holds for level 3. The probability of a transition, either spontaneous or stimulated, is proportional to the product of the number of atoms in the initial state, the density of photons, and the radiative transition rate. This is essentially what is termed Fermi's golden rule. In most commonly encountered systems, the number of atoms in level 1 far exceeds the numbers in other levels; thus, absorption occurs. If the number of atoms in level 2 can be made to exceed the number in level 1, the stimulated emission rate will exceed the absorption rate and net amplification will occur. The system is then said to be inverted. Levels 2 and 1 are termed the upper and lower lasing levels, respectively.

Figure 1. Three and four-level atomic systems
A) Three-level atomic system; B) Four-level atomic system

The number of atoms in level 2 can be made to exceed those in level 1 by various methods. Collisional excitation by electrons and optical pumping by flash-lamp light are two examples. In optical pumping, photons from an intense conventional source such as a flash lamp or an arc lamp are absorbed by the atomic medium and excite atoms from level 1 to level 3. Level 3 then decays, radiatively or nonradiatively, to level 2. When the number of atoms in level 2 exceeds that in level 1, gain is observed. Note that this is an inherently inefficient system because over half of the atoms must be removed from level 1 to achieve unity gain. A system of the type shown in Figure 1A is termed a *three-level system.*

A more efficient laser system is shown in Figure 1B. This is a *four-level system.* Level 1 is the ground state where the unexcited atom lies. Lasing action occurs between levels 3 and 2. Level 2 decays rapidly to the ground state. Level 3 is the upper lasing level and typically has a longer lifetime than other excited levels of the system. Finally, level 4 represents the pump bands from which atoms decay to level 3. Note that this system is very efficient because only enough atoms must be raised to level 3 to exceed the (usually small) thermal population of level 2.

Saturation of gain may occur in either three- or four-level systems when the stimulated emission rate exceeds the pumping rate. In the case of cw lasers, saturation intensity may be defined as the intensity required to reduce the inversion to one-half of its unsaturated value. For pulsed systems, in which pumping is assumed to be negligible for the duration of the laser pulse, it is more convenient to define a saturation fluence as the energy per unit area required to reduce the initial inversion to 1/e of its original value.

2.2. Properties of Light and Laser Light; Diffraction, Interference, and Coherence

Laser light offers the opportunity to easily observe effects due to diffraction and coherence that are not readily apparent with conventional light sources. Conventionally, light is thought of within the framework of geometrical optics; that is, light is considered to travel in rays. This model is valid only in the limit of infinitely short wavelength. Since the wavelength of green light is ca. 500 nm, this is usually a very good approximation. Diffraction is a direct manifestation of the nonzero wavelength of light. The classic example of diffraction of light is the pattern produced at a long distance (compared to the dimensions of the aperture) from a circular aperture illuminated by a monochromatic plane wave. The Airy pattern so produced is shown in Figure 2. The central maximum is surrounded by a series of rings of decreasing intensity, despite the fact that the pattern observed immediately after the aperture is a direct map of the aperture. A less obvious effect is the modification of the phase

of the light. In Figure 2 the phase within each bright ring is constant, but a phase change of π occurs between each of the rings.

Figure 2. The Airy pattern
The plot shows the observed intensity along a diameter of the azimuthally symmetric pattern. The central spot contains 84 % of the energy transmitted by the aperture, and the maximum intensity of the first ring is 1.8 % of the central maximum.

A similar effect is observed for beams with other transverse intensity profiles. An important class of transverse intensity profiles are the Gaussian profiles, whose intensity is characterized by

$$I(r) = I_0 \exp(-r/w)^2$$

where I_0 is the on-axis intensity, r is the distance from the axis, and w characterizes the size of the beam. These are the so-called Gaussian beams produced by a large number of lasers. The propagation of a Gaussian beam with an initially flat phase profile is characterized by spreading of the width of the Gaussian profile and parabolic curving of the phase front of the beam in the direction of propagation. This is important in the discussion of resonators.

A second phenomenon that is readily observed with laser sources is interference. If a screen having two adjacent pinholes is illuminated by a laser source of sufficient coherence, alternating bands, or fringes, of light and dark are observed. The intensity in the dark regions may reach zero, whereas that in the bright regions may attain a maximum of four times the intensity observed when one pinhole is blocked. This phenomenon is a consequence of the wave nature of light, the fact that detectors (the human eye included) respond to power rather than to electric field, and the fact that detectors have a response time far longer than the typical frequency of light (10^{15} Hz). The bright regions are areas in which the phases of the light from the two pinholes are the same and the equal electric fields add. Since the intensity is proportional to the square of the electric field, the intensity is four times that of one pinhole. Dark regions occur where the phases of the light oppose and cancel, leaving a net intensity of zero. Observation of this effect is possible because the light waves from the two pinholes have a fixed phase relationship to each other. If the phase difference between the two beams were to fluctuate in a time period that is short compared to the response time of the detector, uniform intensity with no fringes would be observed. The fixed phase relationship between the light from the two pinholes is termed lateral coherence.

A similar effect can be obtained by delaying part of the laser output with respect to itself. Here, fringes of light and dark occur as a function of the delay. The phase relationship necessary to observe this effect is a fixed phase difference between an earlier and a later portion of the beam. This is termed temporal or longitudinal coherence.

Most conventional sources are essentially incoherent, making interference effects impossible to observe. Most laser sources, on the other hand, exhibit a high degree of both lateral and longitudinal coherence.

2.3. Optical Resonators

Optical resonators are the structures that provide the necessary feedback for laser oscillation. They may be divided into two categories; stable and unstable. Stable resonators are by far the more common.

2.3.1. Stable Resonators

The simplest resonator consists of two opposing mirrors. A resonator is termed stable, if a transverse intensity and phase profile can exist within the resonator that, after reflection from both mirrors and return to original location (i.e., after one *round trip*), remains unchanged. The

transverse intensity and phase of the beam in the resonator are termed its transverse mode structure. Whether or not a particular resonator is stable is determined by the mirror's size, curvature, and separation.

Transverse Mode Structure. Electromagnetic fields in free space are described, in general, by the scalar wave equation. If the approximation is made that the field or light is essentially all propagating within ca. 0.5 rad of the z axis (a very good approximation for most lasers), the wave equation may be simplified to the paraxial wave equation:

$$\nabla_T^2 u(x,y,z) - 2jk\frac{\partial u(x,y,z)}{\partial z} = 0$$

where u is the electric field, $j = \sqrt{-1}$, and $k = 2\pi/\lambda$

(λ is the wavelength). The solutions to this equation in rectangular coordinates are the Hermite–Gaussian modes. In cylindrical coordinates, the solutions are the Laguerre–Gaussian modes. The lowest order solution to this equation is the Gaussian beam mentioned earlier:

$$I(r,z) = \frac{I_0}{w^2(z)}\exp\left[-2r^2/w^2(z)\right]$$

where $w(z)$ is given by:

$$w(z) = w_0\left[1 + (z/w_0)\right]^{1/2}$$

and w_0 is the $1/e^2$ radius at the narrowest part of the beam, termed its waist. The phase and intensity associated with this beam are shown in Figure 3. At $z = 0$, this beam has a waist where the phase front is planar and the beamwidth is narrowest. The beam spreads in either direction from $z = 0$ and acquires a parabolic phase curvature. A stable cavity for a given Gaussian beam can be assembled by placing opposing mirrors in the beam whose curvatures match those of the beam's phase front at the z location. The mirror must be considerably larger than the size of the beam.

The more conventional problem is to determine whether a stable Gaussian beam can propagate between two mirrors of given radii of curvature R_1 and R_2, separated by a distance L. Not all combinations of curved mirrors and separations produce stable cavities. The solution may be determined with the aid of the resonator g parameters:

$$g = 1 - L/R_i i$$

where $i = 1,2$ and R_i is positive if the mirror is concave toward the interior of the cavity. The condition for stability is

$$0 < gg < 121$$

Figure 3. Gaussian beam

Several examples of stable cavities are shown in Figure 4. The *plane-parallel* or *Fabry–Perot cavity* (Fig. 4A), which has $g_1 = g_2 = 1$ and $R_1 = R_2 = \infty$, has only borderline stability. It is often used for solid-state lasers in which the lasing medium acts as a weak positive lens to enhance stability. If the curvatures of both mirrors are decreased equally until $1 > g_1 = g_2 > 0$, a *symmetric resonator* is formed (Fig. 4B). A *half-symmetric resonator* (Fig. 4C) is formed when one of the mirrors in a symmetric resonator is replaced by a plane mirror at $z = 0$ where the phase front is flat. If the radius of curvature of the two mirrors is decreased until $L = R$ ($g_1 = g_2 = 0$), a *symmetric confocal resonator* is formed (Fig. 4D). Because a tilt of either mirror shifts the resonator axis only slightly in the transverse direction, the confocal resonator is relatively insensitive to misalignment. The beam diameter per unit length of this cavity is the smallest of the stable resonators, making the confocal cavity unsuitable for high-power operation. If the radii of curvature of the two mirrors are further decreased until $L = 2R$ ($g_1 = g_2 = -1$), a *concentric resonator* (Fig. 4E) is formed. This resonator is again on the edge of stability. This cavity has a large beam size on the mirrors but a very small beam waist in the center. Care must be taken not to place easily damaged components near this waist. Finally, if one mirror in a concentric resonator is replaced by a plane mirror located at $z = 0$, a *hemispheri-*

Figure 4. Stable resonators
A) The Fabry – Perot resonator has plane-parallel mirrors and is marginally stable $R_1 = R_2 = \infty$). B) The symmetric resonator has equal radii of curvature that are longer than the mirror separation ($R_1 = R_2 > L$). C) The half-symmetric resonator is a symmetric resonator with a plane mirror at the beam waist ($R_1 > L$, $R_2 = \infty$). D) The symmetric confocal resonator has radii equal to the mirror separation and is particularly stable with respect to mirror misadjustments ($R_1 = R_2 = L$). E) The concentric resonator has the sum of the radii equal to the mirror separation ($R_1 + R_2 = L$). F) The hemispherical confocal resonator is a confocal resonator with a plane mirror at the beam waist ($R_1 = 2L$, $R_2 = \infty$).

cal confocal resonator (Fig. 4F) is formed. This resonator is widely used in gas lasers.

The Gaussian beam is the lowest order solution to the paraxial wave equation. An infinite number of solutions exist for the equation, which are referred to as the *t*ransverse *e*lectromagnetic *m*odes (TEM). They are designated by $\mathrm{TEM}_{\mathrm{mn}}$ where m and n are order numbers. The three lowest order modes are shown in Figure 5. Any of these modes can propagate in any of the stable cavities described above. In fact, typical unrestricted laser output will be some combination of many of these modes. The higher order modes are characterized by having progressively larger fractions of their energy at distances further from the z axis. Advantage is often taken of this fact to limit oscillation to the lowest order (TEM_{00} or Gaussian) mode by inserting an aperture into the cavity to increase the losses for the higher order modes while leaving the lowest order mode largely unchanged.

Longitudinal Modes. The modes are restricted further to have an integral number of wavelengths in the resonator. Because the length of a typical laser resonator is of the order of a few centimeters and the wavelength of light is of the order of 5×10^{-5} cm, a large number of wavelengths exist in the resonator. Each frequency ν_q that satisfies the equation:

$$L = qc/2\nu_{\mathrm{q}}$$

where c is the speed of light and q is an integer, defines one longitudinal mode of the cavity.

The frequency separation of longitudinal modes is given by

$$\nu_{q+1} - \nu_q = c/2L$$

Since the frequency band over which the lasing medium exhibits gain (the gain bandwidth) often exceeds $c/2\,L$, many longitudinal modes will experience gain greater than unity and, therefore, oscillate in a typical laser.

Often, no fixed phase relationship exists among these longitudinal modes and an effective reduction of the temporal coherence results. If a fixed phase relationship is imposed between the longitudinal modes, the output of the laser is temporally modulated. Advantage is taken of this fact to produce temporally short pulses by the technique of mode locking.

Figure 5. The three lowest order TEM modes in rectangular coordinates
The $u(x)$ and $u(y)$ functions for the electric field of each mode are also shown schematically. The intensity I is given by $I = [u(x) \cdot u(y)]$

2.3.2. Unstable Resonators

Consider the plane-parallel resonator shown in Figure 4A. If one of the mirrors is given a curvature that is convex toward the interior of the resonator, the simplest form of unstable resonator is formed. The remaining plane mirror is purposely kept small, and the output of the laser is the light leaking around that mirror. The transverse mode structure in this case is a so-called doughnut mode, an annular ring.

Unstable resonators have the advantages that their modes occupy large volumes compared to stable resonators and that they have very high transverse mode suppression, that is, they discriminate against higher order modes. They are particularly useful with high-gain and high-power laser media, such as carbon dioxide, in which large power output is desired and high gain is available to overcome diffraction losses.

2.4. Short-Pulse Generation, Longitudinal Mode Locking

Mode locking is a technique commonly applied to both pulsed and continuous lasers to produce pulses considerably shorter than the resonator round-trip time ($2\,L/c$). Typical mode-locked pulse widths range from 1 ns to < 1 ps.

For a laser with two longitudinal modes of equal oscillating amplitude, the electric field is given by

$$E(t) = \cos(\omega t) + \cos[(\omega + \Delta\omega)\,t]$$

where ω is the radian frequency.

If the output of this laser is monitored with a slow (compared to the frequency of light) detector, the observed intensity is given by

$$I(t) = 2\,[1 + \cos(\Delta\omega t)]$$

Thus, the output is amplitude-modulated at the difference in frequency between the two modes. The peak intensity is four times that of a single mode. The analysis may be extended to N longitudinal modes of equal amplitude locked together with zero phase difference. The intensity is given by

$$I(t) = \frac{\sin^2(N\Delta\omega t/2)}{\sin^2(\Delta\omega t/2)}$$

and is shown in Figure 6. The laser output is a periodic train of pulses of width approximately $\Delta\omega/(2\,\pi\,N)$, with period $2\,L/c$. The peak intensity is N times the intensity of one mode. For a set of modes with a Gaussian intensity distribution in frequency, the laser temporal output is a periodic train of Gaussian pulses.

Figure 6. Intensity versus time for unit amplitude modes locked in phase.
A) Four modes locked in phase; B) Sixteen modes locked in phase

Various techniques can be used to mode-lock a laser in order to produce short pulses. The most common consists of inserting an amplitude modulator into the resonator. If the modulator is driven by a periodic signal which is synchronized with the pulse circulation time inside the cavity, the pulse will be transmitted and the intra-pulse intensity attenuated. An *acousto-optic modulator* uses standing sound waves to produce a spatially stationary, time-periodic phase grating in a transparent solid such as fused silica. Any light traversing the modulator when it has a nonzero acoustic field experiences a diffraction loss. An *electro-optic beam deflector* driven by a periodic signal deflects light out of the resonator when its driving voltage is nonzero. Another type of modulator is the *pockels cell – polarizer* combination. The pockels cell is driven by a periodic signal. When a voltage is applied to a pockels cell it alters the polarization state of the incident laser light, thereby increasing the loss at a polarizing component in the cavity.

2.5. Q-Switching and Cavity (Resonator) Dumping

In many applications, it is desirable to extract the majority of the energy stored in the lasing medium in a single giant pulse. Resonator Q-switching and resonator dumping are two techniques that allow extraction of most of the energy stored in a gain medium in a pulse of 5 – 500-ns duration. Furthermore, Q-switched lasers are often also mode-locked, thereby producing a burst of very short (0.1 – 1 ns), intense pulses.

Many laser media require a much longer time for the pump mechanism to build up a significant inversion than the time required for lasing to build up in the resonator. Consequently, as soon as the inversion has risen to the point where the gain exceeds the losses in the cavity, lasing action begins and clamps the inversion by gain saturation. The total energy stored in the laser medium is thus a function of the loss in the resonator structure. This loss includes all mechanisms for coupling energy out of the resonator, such as output coupling, diffraction losses around mirrors, absorption in internal components, and scattering. A resonator with high loss requires a proportionally higher inversion to initiate lasing. A commonly used measure of the losses in a resonator is the Q factor, which is inversely proportional to the power loss per round trip through the resonator with no gain. The lower the resonator Q, the greater is the inversion required for lasing.

Q-Switching is accomplished by switching the cavity from a low to a high Q value after a large inversion has been allowed to accumulate. The field in the resonator then builds up rapidly because the gain is high compared to

the loss. Pulse growth is limited by gain saturation, which ultimately reduces the gain in the resonator to less than the loss, causing the pulse to decay. Since pulse growth and pulse decay have different mechanisms, the Q-switched pulse shape will be temporally asymmetric with a typically faster rise than fall. The precise shape of the pulse and its asymmetry are functions of how high the gain medium is pumped above the threshold. The pulse is longest and nearly symmetric about its peak when the resonator is Q-switched only slightly above threshold. As the pumping increases, the pulse width becomes shorter and the asymmetry more pronounced.

Several techniques are used for Q-switching a resonator. One of the most common is to insert a pockels cell between crossed polarizers into the resonator. With no applied voltage on the cell, it has no effect on the polarization of the light in the resonator. The resonator effectively has a pair of crossed polarizers inside it, which prevent lasing. At the gain peak, the pockels cell is pulsed to the half-wave voltage which causes it to rotate the plane of polarization of incident light by 90°. This allows light to be transmitted. Lasing then builds up. A second technique is to insert a traveling-wave acousto-optic cell into the resonator. The traveling acoustic wave acts as phase grating which diffracts light out of the resonator. At gain peak, the acoustic drive to the cell is switched off, eliminating diffraction losses. A third technique is to insert a cell containing a saturable dye into the resonator. If the inversion is increased until lasing action begins despite absorption, the absorption saturates and the cell becomes low loss. Such Q-switching with a saturable dye requires careful optimization of dye concentration and resonator parameters. If the saturation of the absorption and its recovery are sufficiently rapid, the dye cell can aid in mode-locking. The dye acts as an amplitude modulator inside the cavity, transmitting the pulse and attenuating the lower intra-pulse intensities. Indeed, not achieving simultaneous Q-switching and mode-locking can be difficult with some dyes.

The Q-switching provides pulse widths in the range of 5 – 500 ns, whereas mode locking provides pulse widths from 1 ns to 0.1 ps. Often, pulses are desired in the range 1 – 10 ns. Cavity dumping is used in this case. Lasing is allowed to build up in a resonator with 100 % reflecting mirrors. At the time of maximum intracavity intensity, an internal switch (typically a pockels cell) is activated, causing all the propagating light in the cavity to be deflected out of the cavity by a polarizer. All of the light in the cavity is deflected out, or dumped, in one cavity round trip; thus, the pulse width is one cavity round-trip time. The pulse shape is nearly rectangular. Cavity dumping can be combined with Q-switching to provide short, high-intensity pulses.

2.6. Nonlinear Optics

The optical properties of materials are independent of the amplitude of the optical field for conventional sources. The advent of lasers allowed generation of optical fields greater than 1 kV/cm, which are necessary to observe nonlinear effects. At these higher field strengths, optical properties (e.g., refractive index) become functions of the field strength or some power of field strength. An infinite number of nonlinear optical interactions exist, corresponding to the infinite number of powers to which the electric field of a laser may be raised. Only those interactions that have become, or are likely to become, technologically important are described here. Further details are given in [2].

The most common nonlinear technique is frequency conversion. This allows generation of additional wavelengths from readily available lasers. Additional frequencies can be generated by harmonic generation, parametric oscillation, or Raman conversion. In *harmonic generation,* multiples of the fundamental laser frequency may be generated in an appropriately phase-matched material. Phase matching requires the fundamental and the harmonic to have the same velocity in the material. Most commonly, frequency doubling or tripling is performed. The intensities required for efficient frequency conversion with current materials can be very high even for lasers. Frequency conversion usually requires Q-switched and/or mode-locked lasers. To obtain sufficient intensity from continuous lasers, tight focus is usually necessary or the frequency-converting material must be placed inside the resonator to take advantage of the large fields there. In *parametric oscillation,* a strong pump beam incident on a nonlinear material is converted into a signal beam and an idler beam,

which have different frequencies. The sum of the frequencies of the signal and idler beams is equal to that of the pump. The advantage of parametric oscillation is that the frequency of the signal beam is continuously tunable. A phase-matching condition again exists among the three beams. Tuning is accomplished by changing the orientation of the nonisotropic nonlinear material. Because parametric oscillation requires a pump with a frequency higher than that of the signal beam, it is most often used to generate infrared or near-infrared light. In *Raman conversion,* the laser frequency is shifted by scattering from molecular vibrations in a material. In Stokes scattering, the laser frequency is decreased by the energy associated with the vibration; the molecule is left in an excited vibrational state. In the much rarer anti-Stokes scattering, the laser frequency is increased by the energy of a molecular vibration, and the initially vibrationally excited molecule is left in a lower state. Raman scattering may also occur from molecular rotations. The range of frequency shifts that can occur is limited by the range of bond strengths available in nature to $400-4000\,\mathrm{cm}^{-1}$. Larger shifts may be obtained by multiple Raman scattering.

Other nonlinear processes are usually encountered in a less beneficial manner. Two-photon absorption and self-focusing are two examples. In *two-photon absorption,* material absorption at twice the frequency of the laser causes significant absorption of laser light, despite the fact that the material may be transparent at the laser frequency. *Self-focusing* is a change in the refractive index of a material with increasing laser intensity. In the majority of materials, refractive index increases with intensity. This causes focusing of the beam, leading to higher intensity and eventual catastrophic damage to the material. These effects are usually seen at intensities of $4\,\mathrm{GW/cm}^2$ in meter-long paths of common optical materials (e.g., glass).

3. Types of Laser and Their Properties

Lasers are conveniently classified according to the type of gain medium used. These include gas, dye, solid state, semiconductor, and others.

3.1. Gas Lasers

Gas lasers can be either pulsed or continuous wave and include the highest power cw lasers. Typically, they are excited by an electrical discharge in the gas. An example is the ubiquitous *helium–neon* (He–Ne) laser. A longitudinal discharge is maintained in a low-pressure mixture of helium and neon. The mixture is predominantly helium with ca. 10 % neon by pressure. The discharge excites the helium, which collisionally transfers the excitation to neon. Lasing can occur at several wavelengths in neon. The highest gain and the first wavelength to lase is in the infrared at 3391.0 nm. The familiar red line is at 632.8 nm. This line is much lower in gain than the 3391-nm line; therefore, care must be taken to suppress the infrared line to achieve laser action at 632.8 nm. Other wavelenghts available from the He–Ne laser are 543.5 and 1523.0 nm.

A second important gas laser is the *carbon dioxide laser.* This molecular laser can be either discharge or radio-frequency (RF) excited. The lasing wavelength is ca. 10.6 µm. Lasing in carbon dioxide occurs between vibrational levels of the molecule rather than electronic levels. The 10.6-µm transition is between the first asymmetric stretch mode and the symmetric stretch mode of the molecule. The transition is broadened by the rotational modes of the molecule. The carbon dioxide laser can be very efficient; electrical to optical power efficiencies of 30 % can be achieved. Furthermore, because the gas can be circulated, very high continuous powers can be achieved, on the order of tens of kilowatts. Because of their high continuous powers, carbon dioxide lasers find wide application in processing of materials, for example, welding, cutting, and heat treatment.

A third important gas laser is the *argon-ion laser* in which the gain medium is singly ionized argon. Inversion is obtained by discharge. Lasing can be achieved at a number of wavelengths, the most important of which are 488.0 and 514.5 nm. Operation in the UV region at 363.8 and 351.1 nm can be achieved by using doubly ionized argon. Argon lasers have the advantage of little or no competition between the major groups of lines; hence, operation can occur at many wavelengths simultaneously. Selec-

tion of a single wavelength can be made by an intracavity prism or by wavelength-selective cavity mirrors. Continuous powers of 10 – 30 W can be obtained by operating at several wavelengths simultaneously.

Other important, but less widely encountered, gas lasers include *nitrogen excimer,* and *chemical* lasers. Further information is given in [3].

3.2. Dye Lasers

Of particular interest to chemists are lasers that are tunable in frequency. Considerable effort has gone into developing organic dyes that lase over a continuous range of frequencies (see also → Laser Dyes). Because of the short upper-level lifetimes characteristic of dyes, excitation is provided by another laser that is absorbed by an absorption band of shorter wavelength than the dye emission band. Short-pulse flash-lamp excitation may also be used. Typical pump lasers are nitrogen, argon ion, and frequency-doubled Nd – YAG (neodymium/yttrium – aluminum – garnet). Dyes are available that span wavelengths from 108.4 to 310.0 nm, but because of the limited tuning range of each dye, ten or more different dyes may be required to cover that range. Lasing in dyes can be continuous or pulsed. For continuous lasing, the dye is circulated through a jet that forms the gain region. Wavelength selection is obtained by using a grating as one of the end mirrors in the cavity or as an intracavity element. Continuous powers of a few tens of milliwatts can be achieved by using continuous laser pumping. Less power is to be expected from the wavelength extremes of any dye or from the more exotic dyes. In pulsed operation, up to 1 J of energy can be obtained, although 0.1 J is much more typical. Repetition rates of >100 Hz can be obtained at these energies. A consequence of the tunability of dye lasers is an extremely broad gain bandwidth. Pulses of <30 fs [4] have been generated by using colliding-pulse mode-locked ring dye lasers. A widely used dye is Rhodamine 640 in methanol – ethylene glycol solvent, tuning from 600 to 700 nm with argon-ion laser pumping.

3.3. Solid-State Lasers

Solid-state lasers are those having a solid active medium rather than a semiconductor (see Section 3.4). In most such lasers, the host medium is a crystal or a glass, and the lasing species is present either substitutionally or interstitially. In color center lasers, the lasing species is actually a type of crystal defect. Many examples of solid-state lasers are available; however, this section discusses only the technologically important Nd^{3+}-based lasers and the tunable Ti^{3+} – sapphire laser.

The neodymium ion, Nd^{3+}, is a rare-earth ion with a partially filled subshell of $4f$ electrons; however, a $5d$ electron participates in the chemical bonding of Nd^{3+} in the solid state. The inner $4f$ electrons are thus shielded to a large degree from the influence of the host, and transitions between $4f$ levels are similar to those of the free ion. Since electric dipole transitions among the $4f$ levels are forbidden by the parity selection rule, lifetimes are long and significant energy storage in the form of inversion is possible. The Nd^{3+} ion is a four-level laser system. Lasing occurs near 1.06 µm. Pumping is achieved by absorption of intense visible light which excites the $4f$ electron into levels lying above the $^4F_{3/2}$ upper laser level. The higher level excited state relaxes to the upper laser level by emission of phonons. This generates heat in the host and is a drawback. Heat in the host causes changes of polarization and phase in the laser beam. Typically, twice as much heat is generated as is energy stored in the form of inversion. Heat removal is facilitated by using a plate geometry for the lasing material, rather than the more familiar rod geometry.

Hosts for Nd^{3+} may be divided into the classes crystalline and glass. Crystalline hosts generally have thermal conductivity an order of magnitude higher than glasses. They also have similarly higher cross sections and, therefore, gains. The Nd^{3+} ion typically substitutes for one of the crystal ions; thus, each Nd^{3+} ion experiences practically the same local field environment. This leads to narrow absorption and emission bands. These attributes make crystalline hosts suitable for cw and quasi-cw applications at relatively high average powers. For example, the Nd^{3+} ion in the crystalline YAG host has achieved > 1 kW of cw power when pumped by

krypton arc lamps. Beam phase and polarization can be greatly reduced by using a plate geometry for the YAG.

Glass hosts can be cast in sizes much larger than those attainable by crystal growth. Glass laser disks of dimensions $30 \times 60 \times 4$ cm have been successfully made. Unlike most crystals, glass is optically and mechanically isotropic and can be cast with superb optical quality. In glass, the Nd^{3+} ion may occupy both substitutional and interstitial sites. Because of the random nature of the neodymium sites in glass, the absorption and emission bands are substantially broadened. For example, the emission bandwidth of Nd – YAG is ca. 1 nm, whereas that of Nd^{3+} in phosphate-based glass is 20 nm. Similarly, the emission cross section is reduced, making possible efficient pumping and storage of energy as inversion. The Nd – glass lasers are thus ideal high-peak-power lasers. Relatively small Nd – glass lasers are capable of achieving a large fraction of a terawatt peak power in pulses of a few picoseconds. Large inertial confinement fusion drivers have achieved more than 50 TW of peak power in a pulse of a few nanoseconds from a multibeam system.

The Ti^{3+} – sapphire laser is an example of a vibronic system that is tunable over 700 – 950 nm. The laser transition consists of the emission of a photon and a quantum of the crystal lattice vibration, a phonon. Energy may be partitioned continuously between phonon and photon, giving rise to the tunability of optical emission. The Ti^{3+} ion consists of an argon core and one $3d$ electron. The fivefold degenerate free-ion d-electron levels are split by the crystal field. The lasing transition is between two of these levels and is thus strongly coupled to the lattice vibrations via the crystal field.

The upper lasing level lifetime is relatively short, ca. $3\,\mu$s at room temperature. Pumping is therefore usually by another laser. Flash lamps, dye lasers near 500 nm, doubled Nd – YAG lasers at 532 nm, and argon-ion lasers operating on blue and green lines have been used. Continuous-wave lasing has been achieved with an argon-ion pump laser. Several hundred millijoules per pulse have been achieved with doubled Nd – YAG pumps. The usual geometry is to mount the crystal on a cold plate and have the pump and output beams collinear. Operation can be achieved readily on a single longitudinal mode. The pulsed output may be doubled to achieve tunability over most of the visible region.

3.4. Semiconductor Lasers

Lasing action can occur in semiconductor p – n junctions. The upper and lower states in this case are the conduction band and the valence band, or the conduction band and an impurity band that lies just above the valence band. Emission of a photon occurs when an electron in the conduction band combines with a vacancy (hole) in the valence band. This requires a partially filled conduction band and a partially empty valence band in a spatially localized region; p-type semiconductors have a partially empty valence band, whereas n-type semiconductors have a partially filled conduction band. When these two types of semiconductor material are brought together in a p – n junction in thermal equilibrium, the energies of the last-filled valence band state in the p-type material and the last-filled conduction band state in the n-type material are equal. Application of a forward bias to the junction raises the energy of the last-filled conduction band in the n-type material. Lasing action can occur in the region of the junction where the bands from the p- and n-type materials are adjacent. This localization can act as an emission guide in one of the spatial dimensions. Laser output is taken through the ends of the device (facets). Typical spontaneous emission times are of the order of a few nanoseconds, and the distance carriers diffuse before recombination can be fairly large (a few microns) for semiconductor-sized structures. This requires large carrier injection rates or, equivalently, junction current to maintain lasing. Structures more complicated than the simple p – n junction are required for cw lasing to confine the carriers to the active region. This is achieved by surrounding the active region or layer with cladding layers in the heterostructure laser diode. Because the cladding layers have a lower refractive index than the active layer, this construction confines the laser output more effectively in one spatial dimension. Further guiding can be obtained by burying the entire heterojunction, except for the facets, in a material of lower index. This is the so-called buried heterostructure diode laser.

Single laser diodes, because of their small size, are limited to modest cw powers of the order of several hundred milliwatts. Pulsed powers can be substantially higher. Diodes may be formed together by semiconductor processing techniques into centimeter-long bars or arrays of diodes. Kilowatts of power per square centimeter of array can be obtained in research devices. Furthermore, the output of individual diodes in these arrays may be phased so that a single mode can be extracted from the device.

Wavelengths of semiconductor lasers are determined by the band gap energy of the materials used to construct them. Al – Ga – As devices operate in the 700 – 900 nm range, whereas In – Ga – As and In – Ga – As – P devices operate at 1200 – 1600 nm. See also → Electroluminescent Materials and Devices, Chap. 5.

4. Uses

The uses of lasers are growing rapidly. This chapter describes those uses that are encountered most commonly.

4.1. Spectroscopy

The laser has revolutionized optical spectroscopy. The tunable, single-frequency dye laser found immediate application in ultrahigh-resolution atomic spectroscopy. Precision measurements of Zeeman, Stark, fine, and hyperfine splittings can be obtained. Because the line width of tunable dye lasers can be <1 MHz, Doppler line widths can easily be measured. Early work centered on atomic and molecular beams, in which thermal motion can be confined to a direction perpendicular to the direction of observation. This largely eliminates Doppler broadening in these observations.

Furthermore, laser techniques have been developed to eliminate the cumbersome molecular beam apparatus required by early experiments. An example of these techniques is saturation spectroscopy, in which the laser is used to label a velocity subset of the molecules under observation. A laser beam is split into two beams, one weaker than the other, that counterpropagate through the sample cell. The stronger of the two, the saturating beam, is amplitude-modulated, either electro-optically or with a chopper. This strong beam partially saturates the absorption seen by the weaker probe beam. By detecting just that part of the probe beam modulated at the same frequency as the saturating beam, only the "tagged" molecules that have interacted with both beams (i.e., those that have no velocity component along either direction of propagation) are observed. Numerous variations on this technique are possible. The same pump – probe beam technique may be used to modulate the polarizability of molecules of a sample between crossed polarizers. When the pump beam irradiates the sample, molecules alter the state of polarization of the probe beam, allowing it to pass the second polarizer. Another, similar technique uses counterpropagating beams tuned to a two-photon transition and detects fluorescence from the upper level of this transition.

Absorption spectroscopy can be performed with unprecedented sensitivity by using tunable lasers. The high collimation of lasers allows long sample paths. Instead of directly detecting the transmitted beam, relative absorption may be measured by detecting the acoustic wave (optoacoustic spectroscopy) or electrical characteristic change (optogalvanic spectroscopy) induced in the sample by a modulated beam. An increase in sensitivity by a factor of $10^5 - 10^6$ over direct techniques can be achieved by placing absorption samples inside the laser resonator and measuring laser output versus tuning frequency. Multiple passes of the light within the cavity effectively multiply the cell length. Ultimate sensitivities are achieved by monitoring fluorescence or photoionization induced by the illuminating beam.

Short-pulse lasers allow time-resolved spectroscopy. The large gain bandwidth of dye lasers also allows the generation of intense pulses that may be as short as a few hundred femtoseconds. Extremely short fluorescence lifetimes and relaxation processes can be investigated by using these lasers. Furthermore, coherent transient phenomena such as self-induced transparency and photon echoes, which yield insight into radiative damping, may be observed with short pulses.

4.2. Remote Sensing

Remote sensing of atmospheric constituents and pollutants became possible with the advent of the laser. The three most common processes used are Raman scattering, linear absorption, and fluorescence. In the majority of applications, a pulsed laser is used with time-gated detection to obtain range information. The pulse is transmitted via a telescope, and the return signal is detected by using either the same telescope or a physically adjacent optical system. By measuring the strength and spectrum of the return signal, data can be obtained on the type and quantity of the sensed species, the thermal conditions, and the velocity field at the remote location.

Raman scattering is particularly useful in detecting species such as water vapor and methane. Raman cross sections are typically small, and the relatively large concentration of these species helps improve the signal-to-noise ratio of the measurement. The first Stokes vibrational line is usually detected. The data are obtained as the typical vertical density profile.

If a laser is available that can be tuned to an absorption feature of the species of interest, the technique of differential absorption lidar (DIAL) may be used (lidar = *li*ght *d*etection *a*nd *r*anging). The return signal for DIAL is generated by Rayleigh scattering from the air molecules and Mie scattering from the atmospheric particles. The DIAL technique compares the magnitude of the return signal with the laser tuned on the absorption feature to the return signal with the laser tuned off the absorption feature. Since the scattering that generates the return signal changes little with the small change in laser frequency, the round-trip absorption from the transmitter to the remote region and back is obtained. By repeating the measurement for a slightly different distance, the actual remote absorption may be determined. This technique has been successfully applied to the detection and profiling of pollutants such as nitrogen dioxide, sulfur dioxide, and ozone.

Finally, if laser-induced excitation of a species is possible, its fluorescence can be detected. This technique is useful for the upper atmosphere where collisional deexcitation rates are reduced. The hydroxyl radical and alkali metals have been detected by using this technique.

4.3. Laser-Assisted Chemical Processes

Laser-assisted chemical processes have not found widespread use in the chemical industry. The reason for their limited application is the high cost of laser light. The few successful applications have occurred when no practicable alternative exists.

One successful application is in nuclear chemistry where lasers have replaced gaseous diffusion and centrifugation in isotope separation. Naturally occurring uranium contains ca. 0.7 % ^{235}U, with the remainder being largely ^{238}U. The isotope ^{235}U is fissionable, whereas ^{238}U inhibits fission by fast-neutron capture and gamma-ray emission. Enrichment of the isotopic abundance of ^{235}U to greater than 3 % is necessary for use in reactors.

A similar application exists in reducing the abundance of the isotope ^{91}Zr in zirconium used in reactor fuel rod cladding. The ^{91}Zr with 11 % natural abundance accounts for 75 % of the thermal neutron capture in the cladding. It is desirable to reduce the abundance of ^{91}Zr to < 3 %.

The process used for uranium enrichment is the atomic vapor laser isotope separation (AVLIS) technique. In this process, advantage is taken of the isotope shift in the absorption spectra of the two uranium isotopes to selectively excite and ionize atoms of ^{235}U, leaving ^{238}U unaffected. This requires that the isotope shift be well-resolved. Because the inner unfilled d- and f-electron shells are shielded by the outer, filled s-electron shell, transitions involving these electrons are spectrally narrow, and the 0.2-cm^{-1} isotope shifts in the spectral absorption lines can be observed. The transitions are spread throughout the visible region. The ionization energy of uranium is ca. 6 eV, and the energy of a green photon is approximately 2 eV. Three photons, each tuned to a specific transition of ^{235}U, are absorbed by ^{235}U atoms until they are ionized. The ^{235}U ions may then be separated from unchanged ^{238}U atoms electrostatically. Atomic uranium is generated by electron-beam vaporization of a uranium melt. Aperturing of the vapor from the melt creates an atomic beam to limit Doppler effects. The requisite three separately tuned photons are generated by dye lasers pumped with a copper-vapor laser. Large, high

repetition rate laser powers, of the order of 100–1000 W, are required for an economically viable facility.

4.4. Metrology

Metrology, in particular precision metrology, is synonymous with the field of optical interferometry which predated the invention of the laser. It was the laser's vastly improved coherence, both spatial and temporal, and its greater brightness that revolutionized metrology. Metrology may be somewhat arbitrarily divided into two broad areas: classical interferometry and holography. In either area, the interference of coherent light permits measurement.

The classic example in interferometry is the Mach–Zehnder interferometer. In this device, a laser beam is split into two beams of equal intensity by an optical beam splitter. The two beams are made parallel by means of a mirror in one beam, and a transparent object is introduced into the other. The two are then combined with another beam splitter. The resulting combined beam has light and dark areas, corresponding to areas in which multiples of a full and a half wave of optical path have been introduced into the sample beam, respectively. By counting these fringes, differences in path of a fraction of the wavelength of light can be measured. By replacing the transparent sample with an optically reflecting surface, surface deformations of the same magnitude may be measured. By counting the number of fringes that pass a point, displacement can be measured; by measuring the rate at which fringes pass, velocity can be measured.

This basic concept may be applied to a large number of measurements. If the reflecting surface in the above example is the wall of a bellows, extremely sensitive measurements of pressure may be made. Similarly, if the reflecting surface is a free diaphragm, an extremely sensitive microphone can be made. Most underwater acoustic sensors are now based on fiber optic implementations of this technique. Temperature can be determined if the thermal expansion coefficient of the transparent plate and the dependence of its refractive index on temperature are known. Advantage may be taken of electro- and magneto-optical effects in transparent materials to measure voltage, electric field, or magnetic field. These techniques are often combined with fiber optics. Sensitive measurements of magnetic fields are now made by measuring the change in optical length of a fiber optic that is coated with a magnetostrictive material. Making the fiber longer increases sensitivity. Any of these measurements can be combined with a pulsed laser to yield high-precision time-resolved data.

Holography (see also → Holography) is similar to interferometry in that the interference pattern between a reference beam and the coherent light reflected by an object is recorded, usually on film. The film is developed and illuminated with a reconstruction beam in the same direction as the original reference beam. The reconstruction beam is diffracted by the interference pattern recorded on the film. The resultant diffracted wave is the same as the original object wave. It contains all the phase information of the original beam and, when viewed with the eye, appears fully three-dimensional.

Holography is used in the measurement of the displacement of surfaces. If holography is performed with a pulsed laser, time-instantaneous images of moving objects may be obtained. Furthermore, if long exposure of a vibrating object is recorded in a hologram, the brightness of the hologram is reduced for those parts of the object that move. The resulting hologram shows a pattern of light and dark fringes corresponding to nodes and antinodes of the vibrational mode.

4.5. Medical Applications

Lasers found their first routine application in medicine in eye surgery, where other techniques were extremely difficult or simply not available.

In certain cases, usually as a result of injury to the eye and sometimes due to aging, the retina may become detached from the back of the eye, resulting in partial or total blindness. In retinal reattachment, a visible laser is focused through the lens of the eye onto the retina and an intense pulse of laser light tacks it back in place.

A similar application is the treatment of diabetic retinopathy. In this condition, small blood vessels on the retina proliferate, degenerate, and hemorrhage. The blood vessels obscure the retina, and blood mixes with the vitreous humor,

further obscuring vision. A low- to moderate-power argon-ion laser focused on the retina is used to destroy excess blood vessels. This technique makes use of the "bloodless" nature of the laser. Blood vessels are cauterized by the laser so that no posttreatment bleeding occurs.

A more recent application involves permanent correction of myopia and astigmatism. In laser keratomy, fine radial incisions are made in the cornea, which accounts for part of the static focusing power of the eye. These incisions flatten the corneal surface, thereby reducing its optical power and restoring sharp vision. The location of the incisions may be varied to correct azimuthally asymmetric visual aberrations. Either an argon-ion laser (with a suitable absorbing dye placed on the cornea) or an excimer laser (whose UV output is absorbed directly by the cornea) may be used. The laser can be used not only to perform surgery but also in a highly attenuated and unfocused mode to sense the shape of the cornea as the operation progresses.

The combination of fiber optics and lasers opens previously inaccessible regions to surgery; an example is laser angioplasty. A fiber optic is a thin (several microns) glass fiber that can transport laser light by total internal reflection. Similarly, a fiber or fiber bundle can transmit diagnostic fluorescence or an image from a remote area. In laser angioplasty, a catheter equipped with one or more optical fibers is inserted into an artery and routed up to a blockage. The laser, usually dye or excimer, is fired and the arteriosclerotic plaque is vaporized. Either the laser energy is absorbed directly by the plaque, or a metal ball is affixed to the end of the fiber and the laser is used to heat the ball to remove the plaque. The latter technique does not allow use of the spectral absorptivity differences between the plaque and healthy vessel tissue to avoid damage to healthy tissue. In more advanced systems, a separate low-power laser pulse is used to excite fluorescence in the artery location where the catheter ends. The fluorescence is carried out of the patient by another fiber and analyzed spectrally. Real-time computer processing of the fluorescence spectra can differentiate between healthy and abnormal arterial tissue, and the high-power laser can be controlled so as to prevent damage. This technique has found greatest success in the treatment of leg arteries. The small arteries that serve the heart are often convoluted, requiring catheters more flexible than those currently available. Rapid progress is expected as catheter technology develops.

Another application combining fiber optics and lasers is the reduction of kidney stones. The laser is again introduced via catherization. A very high-intensity laser pulse is used to rapidly heat and fragment the kidney stone. The resulting pieces are then passed naturally.

Lasers also aid in diagnosis. The prime diagnostic application is in flow cytology. Here, a laser illuminates a narrow glass capillary tube through which flows a stream of cells to be diagnosed. By treating the cell sample with a fluorescent dye that is preferentially absorbed by cancerous cells, a fluorescence detector located downstream of the laser identifies the presence of malignant cells. An alternative technique is to examine the diffraction pattern produced by the cells. The pattern may be analyzed by computer to identify misshapen cells, which are presumably abnormal.

5. Safety

Laser safety requires a knowledge of the hazards presented by a laser or laser system. Several excellent guides to laser safety have been published (e.g., the Laser Safety Guide by the Laser Institute of America) describing proper precautions. Much of what is presented here can be found in more detail in [5].

Hazards presented by lasers can be divided into three categories: ocular, skin, and associated hazards.

Ocular Hazards. The eye transmits light and focuses it onto the retina in the wavelength range 400 – 1400 nm. Because of the collimation of laser light, it is focused to a point on the retina. Depending on the state of dilation of the pupil, the intensity on the retina may be more than 10^4 times that incident on the eye. If sufficient energy enters the eye before the blink response (0.25 s), permanent retinal damage can occur. Direct viewing of the laser beam or a specular reflection presents the greatest danger. Viewing of diffuse reflections presents a lesser hazard because they are imaged onto a finite area on the retina, thereby reducing the intensity.

Blue and ultraviolet laser light emitted by certain types of laser (e.g., excimers) present additional hazards. Blue light in the region from 400 to 550 nm with an intensity too low to trigger the blink response may produce retinal damage. Near-ultraviolet radiation in the 300 – 400-nm region is absorbed by the lens of the eye, leading either to damage there or, in the longer term, to possible cataract formation. Hard ultraviolet radiation from 200 to 300 nm is absorbed by the cornea and can lead to similar damage there. The same considerations apply to the often substantial UV output from flashtubes used as pumps for certain lasers (e.g., solid-state and pulsed dye lasers).

Skin Hazards. The principal skin hazard is the possibility of burns with a laser of sufficient power. Particular care should be taken with lasers in the 300 – 400-nm region. Finally, a skin cancer hazard is associated with exposure to UV lasers in the region 200 – 300 nm.

Some relatively simple precautions greatly reduce the probability of an accident involving the eye or skin. The route of the laser beam and of its specular reflections must be known. Beam blocks or enclosures should be used where necessary. Adequate eyewear should be worn; the exposure should be estimated and the eyewear absorbance at the laser wavelength measured. Lasers should not be operated at eye level. A laser must not be boresighted under any circumstances, even if it is supposedly deenergized. Untrained personnel should not work with lasers.

Associated Hazards. Other hazards are associated with lasers. The greatest danger arises from the high voltage often used. Other hazards arise from gases (e.g., fluorine for certain excimers), chemicals (e.g., solvents in certain dye lasers), fires inadvertently ignited by high-power (a few watts) cw lasers, and cryogenic gas hazards. In cutting and drilling applications, gaseous and particulate products may represent a respiratory hazard. Most of these dangers can be handled in the same manner as in nonlaser applications; for example, adequate insulation and venting must be used when handling cryogenic gases for lasers. In the case of high-power cw lasers, beam dumps of adequate absorption with sufficient thermal mass should be used. The chemical safety data sheets for dyes and solvents used in any laser should be read carefully for proper handling procedures. Laser gas handling manifolds should be designed specifically for the type of gas involved. Adequate venting and particulate filtration should always be provided in materials-processing applications.

The high-voltage hazard deserves special mention because of the fatalities it has caused among laser workers. Commonly accepted safety procedures for working with high-voltage sections of a laser should always be followed. High voltages should be enclosed in interlocked enclosures. Energy storage capacitor circuits should be equipped with some form of "soft discharge" capability that occurs on power down and interlock violation. Manual grounding sticks should be used on high-voltage parts prior to servicing. Workers who are tired, hungry, medicated, agitated, or otherwise incapable of concentrating should never work on high voltage. No one should work alone on high voltage. Metallic objects such as rings and watchbands should not be worn. All floors are to be considered conductive. Workers should stand on an insulating dry mat and use only one hand when troubleshooting. Emergency procedures for aiding victims of electrical shock should be posted.

Laser Classification. All lasers are classified according to the potential hazard that they represent. The classification described here is due to the American National Standards Institute (ANSI), standard Z-236.1, "Guide for Safe Use of Lasers (1986)." A brief description of each classification follows:

Class 1	No hazard exists.
Class 2 (a)	Lasers present no hazard for direct viewing up to 1000 s.
Class 2 (b)	Lasers do not present a hazard for direct viewing because of the normal blink response.
Class 3 (a)	Lasers present an immediate hazard if viewed with collection optics.
Class 3 (b)	Lasers are hazardous if viewed directly. Diffuse reflections are usually not hazardous except with higher powered lasers.
Class 4	These are the most hazardous lasers. Diffuse reflection is hazardous. Fire and skin hazards exist.

1. Introduction and History

In past centuries defecation induced by orally or rectally administered medications was widely applied by the medical profession. This practice, like phlebotomy, was intended to help cure ailments whose origin was often unknown.

Purgation was highly valued in earlier times, because knowledge of physiological and pathophysiological interactions was limited. Today however, medical science has a clear understanding of how, when, and where the use of laxatives is clinically indicated. Although this should have considerably reduced their use, laxatives are often important ingredients of pharmaceuticals which are designed to help achieve rather dubious goals (blood cleansing, alleged reduction in body weight). Their popularity is often further increased by reference to their "natural", "biological", or plant origin. The consumer is deliberately misled: the active ingredients are chemically clearly defined compounds – it is irrelevant whether they are produced synthetically or derived from plants.

A large proportion of laxatives or laxative-containing compounds are consumed without a sensible therapeutic goal and as uncontrolled self-medication. The dangers involved with such behavior, particularly after long-term use, (e.g., functional and morphological disturbances of the gastrointestinal tract; Na^+, K^+ and water loss; insufficient degradation and absorption of essential nutrients; secondary hyperaldosteronism) are often disregarded.

Mastication initiates the digestive breakdown of solid foods. Thorough chewing facilitates the chemical degradation of the nutrients. Saliva, constituents of gastric fluid and bile, pancreatic secretions, and enzymes from the intestinal epithelial cells cleave proteins, fats, and carbohydrates into absorbable compounds. Furthermore, water, vitamins, and minerals are absorbed from the intestinal lumen and enter the blood and lymph fluid. However, electrolytes and water are not merely absorbed, they can also be secreted back into the intestinal lumen by the action of various laxatives. The solid matter reaching the rectum consists of nondigestible material (cellulose, intestinal bacteria) and water.

Two vagus-dependent neuronal plexus (Plexus myentericus and Plexus submucosus) are predominantly responsible for the motor

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_183

control of the intestinal musculature. Sympathetic nerve fibers from the ganglion coeliacum innervate the musculature and the blood vessels vascularizing the intestine. The plexus are responsible for two types of coordinated motor activity. The first type – nonpropulsive segmentation contraction – is a result of localized constrictions and dilations of the intestinal lumen and leads to a mixing of the contents in the small and large intestines. The second type of motor activity – propulsive contractions – occurs several times a day and causes the fecal mass to be transported in the direction of the rectum. The intensity and frequency of the contractions depend on the degree of intestinal filling and the associated stimulation of intrinsic stretch receptors. From about two years of age onward, the cerebral cortex also influences the propulsive contractions. The initiation of defecation is then not dependent solely on autonomic control, but is also subject to conscious influences. If the physiological reflex resulting from the internal pressure stimulus is repeatedly suppressed, the reflex threshold is raised so that a greater internal pressure is required to initiate defecation. Since prolongation of the retention time of the feces in the rectum is associated with absorption of water, inspissation of the feces results; this is often the reason for obstipation. Emotional occurrences can accelerate defecation.

The individual defecatory rhythm of healthy adults varies considerably (1 – 4 times per day up to once every second or third day).

Obstipation can be caused by spastic contractions of the intestinal musculature with uncoordinated transport, by atonic colonic and rectal musculature, as well as by insufficient excitability of the defecatory reflex (dyschezia).

Obstipation can also be associated with other diseases, such as obstructions of the gastrointestinal tract, appendicitis, hemorrhoids, or anal fissures. Nonsteroidal anti-inflammatory agents, sedatives, analgesics, anticholinergics, opiates, antacids, and substances with an anticholinergic action in addition to their primary pharmacologic effect can all cause obstipation.

A very important factor in the development of obstipation are nutritional mistakes, especially when the diet contains insufficient indigestible material (e.g., cellulose) or when physical activity is restricted.

Therapy for obstipation depends on the underlying causes. A prerequisite for the short-term medically correct use of laxatives is to rule out beforehand those causes that cannot be cured or can only be cured by other therapies. The use of laxatives is thus limited to the following clinical indications:

1) Emptying of intestinal contents before surgical, endoscopic, or radiographic procedures
2) Facilitation of defecation in case of hernias and anal fissures by reducing the consistency of the stool; avoiding an increase in intraabdominal pressure when there is danger of apoplexia
3) Increased elimination of poisons taken orally

Finally, cases of chronic obstipation exist which do not improve even after a change in life style and diet. These cases require a continued careful treatment with laxatives.

Laxatives are administered to soften inspissated feces and to initiate the defecation. Laxatives can therefore be divided into four groups according to their mode of action.

1) Emollients (lubricants)
2) Bulking agents
3) Osmotically active substances
4) Antiabsorptive and secretion-stimulating substances and compounds that selectively stimulate the transport capacity of the colon

2. Types of Laxatives

2.1. Emollients (Lubricants)

2.1.1. Paraffinum Liquidum

Paraffinum liquidum (mineral oil) (DAB 9, Ph. Eur.) specific gravity 0.827 – 0.892 is still occasionally used. If taken with food, it can be absorbed to a small degree and thus lead to the formation of foreign body granulomas. Furthermore, its use can lead to hypovitaminosis of fat-soluble vitamins. For these reasons it should only be used therapeutically in case of organic solvent poisonings.

The single dose for adults is one tablespoon. Mineral oil acts after 8 – 12 h.

The simultaneous use of dioctyl sodium sulfosuccinate with paraffin can lead to an increased absorption of the latter. These two substances should therefore not be used together.

Trade Names. Obstinol Mild (Thiemann); as an additive to Salus-öl (Salushaus); Sanato-Lax (Hotz); Agarol (Goedecke); Sanato-Lax-forte (Hotz).

2.1.2. Glycerol (→ Glycerol)

Glycerol [*56-81-5*], 1,2,3-propanetriol, $C_3H_8O_3$, M_r 92 (DAB 9, Ph. Eur.), is a clear, colorless strongly hygroscopic fluid, which acts mainly because of its osmotic effect. It can soften hardened feces and also works as a lubricant. Furthermore it stimulates rectal peristaltis.

Glycerol can be used either in suppository or enema form. The dosage for babies and infants up to six years of age is 1.0 – 1.5 g, for adults 1 – 3 g. It acts within ca. 2 h.

Trade Names. Babylax (Dentinox); Glycilax (Engelhard); Microklist (Pharmacia); Bébégel (Plantier); Glysolax (Cooper).

2.1.3. Dioctyl Sodium Sulfosuccinate

Dioctyl sodium sulfosuccinate [*577-11-7*] (docusate sodium, DONSS), $C_{20}H_{37}NaO_7S$, M_r 444.5, (U.S.P. XXI, The Extra Pharmacopeia, 28th ed. Martindale, 1982) is a wax-like substance which is sparingly water-soluble (1.5 wt %). It is synthesized by reaction of ethylhexanol with maleic anhydride and introducing the sulfonic acid group with sodium hydrogensulfite [9].

The compound has a softening effect and reduces surface tension. It therefore is supposed to impede excessive inspissation of the intestinal contents and acts as a lubricant.

In many European countries and in the United States it is available as a pure substance in 100 mg capsules or as a syrup. In the Federal Republic of Germany it is only available in combination with other laxatives.

Trade Names. Agaroletten (Goedecke); Florisan (Biotherax); Klyxenema (Ferring/Braun); Docusate Sodium (Lederle Laboratories); Doctynol (Astra); Regulex (Ayerst).

2.2. Bulking Agents

2.2.1. Agar

Agar [*9002-18-0*] (DAB 9, Ph. Eur.), is a constituent of cell walls from algae (→ Polysaccharides, Chap. 6.) which belong to the *Gelidium* species (mainly *Rhodophyceae* species). Approximately 90 % of it consists of polysaccharides with acidic groups. Their matrix is formed by D- and L-galactose units and always contains small amounts of galacturonic acid. The acidic groups are present partially as calcium, magnesium, sodium, and potassium salts.

Agar is produced by extraction of the algae with boiling water. The hot extract is filtered, concentrated and dried. Agar is tasteless, odorless and varies from colorless to slightly yellow. It is strongly hygroscopic and has a strong swelling capability. Agar is not metabolized in the gastro-intestinal tract.

The dosage is 4 – 16 g, one to two times per day. It acts within 8 – 12 h.

Trade Names. Agarol (Goedecke); Laxatan (Divapharma-Knufinke).

2.2.2. Linseed

Linseed, Lini Semen (DAB 9, Ph. Eur.) is the ripe dried seed of *Linum usitatissimum*. It contains 30 – 40 wt % fatty oils, 25 wt % protein, and 3 – 20 wt % mucilage. Through their swelling capability the linseed polysaccharides increase the volume of the stool by absorbing water, stimulate peristalsis and accelerate defecation. They are not absorbed. The therapeutic dose is 20 – 50 g. Linseeds act after 12 – 24 h.

2.2.3. Plantago Seed

Plantago seed, Psyllii Semen, (DAB 9) consists of the ripe seeds of *Plantago psyllium* and *Plantago indica.* Indian Plantago seed, *Plantaginis ovatae* semen, are the seeds of *Plantago ovata* and *Plantago ispaghula.* The seeds contain 10 – 12 % mucopolysaccharides which form two fractions, one is soluble in cold water, the other in hot water.

Mixed with an equal portion of water, the seeds form a mucilaginous mass. Not only the seeds, but also the seed coats are used (Plantaginis ovatae testa).

The dosage is between 2.5 and 5 g. Plantago seed is supposed to act within 12 – 24 h.

Trade Names. Agiolax (Madaus); Psyllium (Kneipp); Laxiplant (Schwabe); Naturacil (Mead Johnson & Comp).

2.2.4. Methylcellulose

Methylcellulose (methylcellulosum, DAB 9, Ph. Eur.) is a partially methylated derivative of cellulose (→ Cellulose Ethers, Chap. 3.). It is hydrophilic and nonabsorbable. With addition of water an opalescent, viscous colloidal solution is formed. This solution softens stool within 1 – 3 d. The commonly used therapeutic dosage is a total of 4 – 6 g per day for adults taken in 2 – 3 divided portions. The dosage for children is 1.0 – 1.5 g.

Trade Names. Laxariston-Granulat (Steiner); Methocel (Dow Chemical); Cellothyl (Warner – Chilcott); Cellucon (Medo-Chemicals).

2.2.5. Tragacanth (→ Polysaccharides, Chap. 8.)

Tragacanth [*9000-65-1*] (tragacantha, DAB 9, Ph. Eur.) is the hardened gum which is secreted by the trunk and branches of members of the *Astragulus* species, especially *Astragulus gummifer* as well as *A. microcephalus*. It is odorless and has a bland, slimy taste. Pulverized it is white or off-white.

Tragacanth is a complex mixture of polysaccharides. It is only partially water-soluble (15 – 40 %). The water-insoluble but strongly swellable main fraction is called bassorin, the water soluble fraction is called tragacanthin. One part tragacanth and ten parts water forms a mucoid gel.

The recommended dosage is one heaping teaspoon of the granulated material taken mornings and evening with plenty of water.

Trade Name. Normacol (Asche).

2.2.6. Wheat Bran

Wheat bran contains the seed husks which are separated from the wheat kernel during milling and are extracted from the flour by sifting. It contains predominantly (> 40 %) indigestible cellulose as well as 15 – 18 % protein and vitamin B_1 and E. Consumption of approximately 6 g of bran already leads to a noticeable increase in fecal volume. Innumerable commercial products contain bran.

Side Effects of Bulking Agents. Bulking agents merely represent an expensive alternative to a fiber-rich diet. As dried substances they require large amounts of fluids to be consumed simultaneously to prevent obstipations or the forming of conglomerates in the intestines.

2.3. Osmotically Active Substances

2.3.1. Sodium Sulfate

Sodium sulfate [*7757-82-6*] (Natrii sulfas decahydricus, Natrium sulfuricum, Glauber's salt), $Na_2SO_4 \cdot 10\,H_2O$ (Ph. Eur.), is absorbed poorly in the gastrointestinal tract and binds water. Thereby, an osmotically equivalent amount of fluid is retained in the intestinal lumen and prevents hardening of feces. Sodium sulfate should never be used as a hypertonic solution because of the danger of dehydration and thrombosis.

The best result is achieved with a solution of 20 g of the salt dissolved in 500 mL of water, which is almost an isotonic solution. It acts after 2 – 4 h. With prolonged use, sodium retention, edema and hypertension can occur. Therefore, Glauber's salt should only be used with care by hypertonics.

2.3.2. Magnesium Sulfate

Magnesium sulfate [*7487-88-9*] (Epsom salts) $MgSO_4 \cdot 7\,H_2O$, (Ph. Eur.), exerts its laxative effect in the same way as Glauber's salt. Inadequate magnesium ion excretion can occur leading to muscular weakness, reflex deficits and hypotension as side effects in pediatrics as well as with renal insufficiency.

2.3.3. Sugars and Sugar Alcohols (→ Sugar Alcohols, → Lactose and Derivatives)

Mannitol and sorbitol act similarly to the salinic laxatives and are scarcely absorbed.

Mannitol. D-Mannitol, [*69-65-8*] (DAB 9), $C_6H_{14}O_6$, M_r 182, *mp* 166 – 168 °C, is a sweet-tasting hexavalent alcohol which is widespread in nature, is easily soluble in water, and slightly soluble in ethanol. Mannitol is produced by catalytic hydrogenation of sucrose or invert sugar.

Sorbitol. Sorbitolum [*50-70-4*], D-glucitol, $C_6H_{14}O_6$, M_r 182,

mp 110 – 112 °C (anhydrous substance) (DAB 9, Ph. Eur.) cristallizes with 0.5 and 1 mol of water. It is a white, sweet-tasting compound which is highly soluble in water and occurs naturally in many plants.

Sorbitol is produced commercially by pressure hydrogenation of D-glucose [10].

Dosage: 5 – 15 g total daily taken in several divided doses.

Trade Name. Klysma-Sorbit (Pfrimmer).

Lactose (Lactosum) [*63-42-3*], 4-*O*-β-D-galactopyranosyl-α-D-glucopyranose monohydrate $C_{12}H_{22}O_{11} \cdot H_2O$ (DAB 9), M_r 360.3, *mp* 201 – 202 °C, is a white crystalline substance. It is easily soluble in water, almost insoluble in ethanol. Commercially, lactose is extracted from whey (see → Lactose and Derivatives, Chap. 1.2.). Lactose is hydrolyzed in the intestine. Its metabolites lower the pH value of the feces.

Lactulose [*4618-18-2*], 4-*O*-β-D-galactopyranosyl-D-fructose, $C_{12}H_{22}O_{11}$, M_r 342.30, *mp* 169 °C, is a sweet-tasting compound which is easily soluble in warm water [11]. Lactulose is a synthetic disaccharide consisting of D-galactose and D-fructose (see → Lactose and Derivatives, Chap. 2.1.). It is produced by alkaline epimerisation of lactose.

Lactulose passes through the stomach unaltered and is not hydrolyzed by the enzymes of the small intestine. Beginning in the large intestine the microflora cleaves it into short-chained fatty acids, especially lactic and acetic acids.

Lactic and acetic acids acidify the intestinal contents, retain water in the lumen and stimulate large intestinal peristalsis. Through the change in pH the intestinal bacterial flora is also altered. Lactulose can be used as a mild laxative.

10 – 35 g are recommended as a single dose. The substance acts within 8 – 10 h.

Trade Names. Bifiteral (Duphar); Laevilac (Atmos).

2.4. Antiabsorptive and Secretion-Stimulating Substances and Compounds that Selectively Increase the Rate of Colonic Peristalsis

These substances inhibit the absorption of fluid and sodium ions in the large intestine. Only castor oil is an exception because it is already active in the small intestine. Furthermore, they cause an influx of water into the intestinal lumen together with sodium, potassium, calcium and chloride ions. Thus, the feces are softened and their volume is increased. The resultant distension of the intestinal wall activates the defecation reflex. A direct influence on the visceral smooth muscles increasing peristalsis has to be taken into consideration as a further mode of action of this group of compounds.

2.4.1. Synthetic Diphenol Laxatives

These compounds act in the large intestine. Phenolphthalein, the oldest member of this group, was accidently discovered at the beginning of this century.

Phenolphthalein. Phenolphthalein [*77-09-8*], 3,3-bis-(4-hydroxyphenyl)-1-(3H)-isobenzofuranon, $C_{20}H_{14}O_4$, M_r 318, *mp* 258 – 260 °C, forms colorless crystals that are

almost insoluble in water but easily soluble in ethanol. It is produced by the condensation of phenol with phthalic anhydride in the presence of concentrated sulfuric acid [12].

Approximately 15 % of any dose of phenolphthalein is absorbed by the organism and then excreted via urine. If the urine is alkaline a red coloration can occur. The rest (ca. 85 %) is excreted with the feces. The therapeutic dosage is 100 – 200 mg and leads to defecation within 6 – 10 h. Clinically, sporadic albuminuria and hemoglobinuria as well as allergic symptoms have been reported.

Trade Names. Agarol (Goedecke); Obstinol (Thiemann, Chefaro).

Bisacodyl [*603-50-9*], 4,4′-(2-pyridinyl methylene) bisphenol diacetate, bis-(*p*-acetoxyphenyl)-(2-pyridyl)-methane, $C_{22}H_{19}NO_4$, M_r 361, *mp* 136 – 138 °C, forms colorless crystals which are nearly insoluble in water but soluble in acetone, methanol and ethanol. It is produced by condensation of 2-pyridinealdehyde with phenol in the presence of dehydrating compounds. Subsequently, the phenolic hydroxyl groups are acetylated [13].

The compound is active after oral and rectal administration. Bisacodyl is available in 5.0 mg enteric coated tablets and in 10.0 mg suppositories. For improved colonic inspection it is also available in liquid form.

The clinical dosage is generally 10.0 mg. The tablets act after 6 – 8 h, suppositories within 15 – 30 min.

Bisacodyl has been used therapeutically since 1952. According to the common scientific opinion its mode of action is as follows: First, the two acetyl groups are split off in the small intestine. This is followed by (1) the absorption of the diphenol moiety, (2) enterohepatic cycling, (3) conjugation with glucuronic acid, and (4) the repeated excretion into the intestinal lumen with bile. From here the conjugates are transported to the large intestine. The microflora cleaves them to the active free diphenol, which stimulates the intestines. The long period of 6 – 8 h between oral administration and the drug's effect is explained by this long "metabolic detour" [14], [15].

However, studies in humans [16], using pH controlled tablets which release the substance in the large intestine, have shown that only small amounts of the cathartically active 4,4′-(2-pyridinyl methylene)bisphenol are absorbed. The same holds true for the administration of suppositories. No correlation between plasma concentrations and the effect of the substance could be found. It is postulated that the laxative effect is a result of interactions or direct contact of the active substance (bisphenol) with sensory nerve endings situated in the lower part of the alimentary tract. This produces increased peristaltic contractions of the colon and would explain the rapid onset of action after rectal administration.

Trade Name. Dulcolax (Dr. Karl Thomae); Contalax (Riker); Theralax (Beecham); Nourilax (Organon).

Sodium picosulfate [*10040-45-6*], 4,4′-(2-pyridinylmethylene)bisphenol, bis(hydrogensulfate) (ester), disodium salt, $C_{18}H_{15}NO_8S_2 \cdot 2\,Na$, M_r 481, *mp* 272 – 275 °C (decomp.), forms colorless crystals (recrystallized from ethanol) which are easily soluble in water.

The substance is synthesized by the reaction of 4,4′-(2-pyridinylmethylene)bisphenol with chlorosulfuric acid in the presence of pyridine. The sulfuric acid ester is converted to its sodium salt with sodium hydroxide [17].

Sodium picosulfate can be much more easily produced by reaction of 4,4′-(2-pyridinylmethy-

lene)bisphenol with the easily available pyridine – sulfur trioxide adduct in dimethylformamide and subsequent addition of sodium carbonate [18].

Sodium picosulfate is available as 5 mg tablets as well as in an aqueous solution (7.5 mg/mL). The dosage for adults is 5 – 10 mg, for children four years or older approximately half this dosage. The substance acts in 5 – 8 h. The concurrent use of antibiotics can block the action of sodium picosulfate. It is only effective after oral not after rectal administration.

Sodium picosulfate is not absorbed to any appreciable extent in the gastrointestinal tract. Intestinal sulfatases are required to liberate the active diphenols by hydrolyzing both of the sulfate groups. In small children the sulfatases are generally not present.

Trade Name. Laxoberal (Biotherax).

2.4.2. Naturally Occurring Laxatives

Castor oil (Ricini oleum), (DAB 9, Ph. Eur.), is extracted from the seeds of *Ricinus communis* by cold pressing. It is a viscous fluid with a characteristic taste. The color varies from light yellow to colorless. It consists mainly of the triglyceride of ricinoleic acid.

The inactive triglyceride is hydrolyzed in the small intestine by pancreas lipases, forming glycerol and ricinoleic acid.

Ricinoleic acid [*141-22-0*], $C_{18}H_{34}O_3$, M_r 298.5 inhibits the reabsorption of fluid and electrolytes and stimulates peristalsis. Within a short time (2 – 4 h), defecation results because of the accumulation of fluids and stimulation of enteral motility. This effect can be so pronounced that it may take several days until intestinal filling is sufficient again to initiate the physiological defecation reflex. Therefore, castor oil should only be used in cases of acute obstipation or prior to diagnostic procedures, if necessary. Chronic use can lead to colics, dehydration, disturbances in electrolyte balance, malabsorption of vital substances as well as damage of the intestinal mucosa. Ricinoleic acid is absorbed and metabolized in the same way as other fatty acids.

The therapeutic dosage is between 15 and 60 mL. Because of its bad taste capsules should be favored.

2.4.3. Anthraquinone Laxatives

A number of laxatives of vegetable origin (aloes, cascara, frangula, rhubarb, senna) owe their activity to anthracene derivatives such as anthraquinones, anthrones, and dianthrones. This group of drugs is called anthraquinone laxatives, because substances of this type were the first to be isolated from these plants.

These natural products have been used as laxatives for thousands of years. At present the primary plant materials or their extracts are widely used, also in selfmedication. For reviews of many aspects of these laxatives see [19], [20].

Chemical Properties. In the plants *O*-glycosides of 1,8-dihydroxyanthraquinones occur together with their reduced forms, the anthrones and dimers of the latter, the dianthrones. Sometimes also *C*-glycosides are present.

A large variety of 1,8-dihydroxyanthracene derivatives occur because of substitution of the hydrogen at C-6 by a hydroxyl or methoxy group and/or methyl, hydroxymethyl or carboxyl substitution at C-3.

	R_1	R_2
Chrysophanol	$-H$	$-CH_3$
Physcion	$-OCH_3$	$-CH_3$
Emodin	$-OH$	$-CH_3$
Aloe-emodin	$-H$	$-CH_2OH$
Rhein	$-H$	$-COOH$

Mode of Action. Anthracene derivatives induce defecation by stimulating propulsive peristaltic activity of the colon through local irritation. *The absorption of electrolytes and water* from the colon is altered producing net fluid accumulation and laxation by (1) inhibiting intestinal Na^+-Ka^+-ATPase, (2) production of leaktight junctions in the mucosa of the colon, and (3) maybe by increasing the synthesis of prostaglandins and cyclic AMP [20], [21].

Following oral administration the anthracene glycosides are only slightly absorbed from the small intestine. Their sugar residue facilitates their transport to the site of action, the colon.

There most of the glycosides are hydrolyzed and reduced by colonic flora to anthrones, being the active form [22].

The free aglycons exhibit little therapeutic activity. Dianthrone glycosides are highly active, anthraquinone glycosides less active. Anthrone glycosides act more drastically causing discomforting griping [20], [21].

Raw Materials. *Aloes* (Ph. Eur. 3) consists of the dried juice of the leaves of *Aloe barbadensis* (Barbados aloes) containing 28 wt % of anthracene derivatives or from the leaves of *Aloe ferox* (Cape aloes) containing 18 % of anthracene derivatives. The main constituent is: barbaloin (aloin), i.e., aloe – emodin anthrone-10-*C*-glycoside

Barbaloin (aloe-emodinanthrone-10-*C*-glycoside)

In Cape aloes also aloinosides (*O*-glycosides of aloin) are present.

Standardized aloes dry extract (Ph. Eur. 3) is prepared from both types of aloes containing 20 wt % of anthracene derivatives.

Cascara (Ph. Eur. 3) consists of the dried bark of *Rhamnus purshianus* (Pacific coast of North America) containing 8 wt % of hydroxyanthracene glycosides. The main constituents are: cascarosides (C-10 isomers of 8-*O*-glycosides of aloin and 11-desoxyaloin) and *O*-glycosides derived from emodin, aloe – emodin and chrysophanol.

Frangula bark (Ph. Eur. 3) consists of the dried bark of *Rhamnus frangula* (Europe) containing 7 wt % of glucofrangulins. The main constituents are: glucofrangulin (emodin-6-*O*-rhamno-8-*O*-glycoside) and frangulin (emodin-6-*O*-rhamnoside).

Frangula bark dry extract standardized (Ph. Eur. 3) is prepared from Frangula bark, it contains not less than 15 wt % and not more than 30 wt % of glucorangulins.

Rhubarb (Ph. Eur. 3) consists of the dried rhizome of *Rheum palmatum* and *Rheum officinale* originally from China, but now also cultivated in Europe. It contains 2.2 wt % of hydroxyanthracene derivatives. Its main constituents are: *O*-glycosides of chrysophanol, physcion, emodin, aloe-emodin, rhein; dianthrone glycosides (i.e. sennosides A, B, C, D, E, F).

Senna leaf (Ph. Eur. 3) consists of the dried leaflets of *Cassia senna* (i.e., *C. acutifolia*) known as Alexandrian or Khartoum senna or of *Cassia angustifolia* known as Tinnevelly senna (India), containing 2.5 wt % of hydroxyanthracene glucosides.

Sennoside A

Senna leaf dry extract standardized (Ph. Eur. 3) is prepared from Senna leaf, it contains not less than 5.5 wt % and not more than 8.0 wt % of hydroxyanthracene glucosides. *Senna pods Alexandrian* (Ph. Eur. 3) consists of the dried fruit of *Cassia senna*, they contain not less than 3.4 wt % of hydoxyanthracene glucosides. *Senna pods Tinnevelly* (Ph. Eur. 3) consist of the dried fruit of *Cassia angustifolia*, they contain not less than 2.2 wt % of hydroxyanthracene glucosides. The main constituents are dianthrone glycosides (sennosides A, B, C, D).

Chemical Analysis. For identification and determination the Bornträger test (or a modification) is used: anthraquinones produce a red color after addition of alkali. Dianthrones and anthrones give this test only after oxidation to anthraquinones [20], [21], [23]. HPLC methods for the determination of the different anthracene derivatives also exist [24].

Toxicology. With the exception of aloes which is very irritating, the anthraquinone laxatives are mild laxatives. However, they are habit-forming and long-term use may result in laxative dependance and loss of bowel function (cathartic colon). Long-term use can produce loss of electrolytes and melanosis coli, a reversible pigmentation of the colonic mucosa. Anthracene derivatives may be distributed in small amounts into the milk of nursing women. Therefore, prolonged or excessive use of these products should be avoided.

1. Introduction

Charles A. Sutherland, Edward F. Milner, Albert Melin

The metal lead remains a major nonferrous commodity in modern industry as it has been from antiquity. In 1989 lead consumption in the nonsocialist world was estimated to be 4.5×10^6 t, which is well below the capacity of the primary producing and recycling plants. Concern about the toxicity of lead has brought about substitutions in some uses and proscriptions in others; consequently, the lead market is now dependent on the lead storage battery. Growth in the transportation field, principally in conventional internal combustion engine automobiles, has been the main factor in sustaining a modest growth in lead consumption of around 2.4 % in 1988. The consumption of lead in other use areas (including the drastically reduced gasoline additive market, pigments, ammunition, solders, plumbing, and shielding) amounts to less than that in the battery market. Recent discoveries in North America, Australia, South Africa, and China have brought economic lead ore reserves to a level comfortably above expected consumption.

History. The knowledge and use of lead goes back as far as 5000 B.C. to the ancient Egyptians. The metal was used extensively by the Phoenicians, Romans, Indians, and Chinese. The first lead mines in Spain were operated around 2000 B.C. The uses of the metal included weight standards, coinage (ultimately replaced by silver), statuary, sheathing and lining, trinkets, anchoring of iron rods, and making of seals. The Greeks operated lead mines at Laurium in the fifth century B.C. and the Romans mined in the Rio Tinto region of Spain in 300 B.C. The Romans used lead extensively for water piping; indeed latin " plumbum " for lead came from the word for a water spout, and from it has come the name plumber. They also used lead for soldering, in sheets for inscribed lettering, and for preparation of lead oxides. Lead uses increased in the Middle Ages with supporting mines appearing in England, Germany, Bohemia, and other parts of Europe. Lead roofing, lead " cames " in stained glass windows, guttering, drain pipes, and later type founding were additional uses that continue today. Lead received considerable attention from the alchemists. Older uses of lead as material for projectiles expanded considerably with the invention of firearms.

In the nineteenth century, the United States entered the lead production industry because of its major natural resources, and was followed by Australia and Canada. In the twentieth century the appearance of the automobile, chemical, and machine industries created large new uses for lead in gasoline antiknock additives, bearing and plumbing alloys, accumulator

batteries, and chemical equipment. Modern uses include glass making, sound attenuation, and radiation shielding.

2. Properties

Charles A. Sutherland, Edward F. Milner, Albert Melin

The element lead, Pb [7439-92-1], A_r 207.21, is a lustrous metal. When freshly cut, surfaces are bluish white but oxidize readily to the familiar dull grey color. Lead is located in group 14 of the periodic table. The element displays valences of + 2 and + 4 as indicated by its electronic configuration:

$$(1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 6s^2 6p^2)$$

This permits attainment of stability by donation of two or four electrons.

Lead Isotopes. Lead (atomic number 82) has four naturally occurring isotopes; mass numbers listed in order of abundance are 208 (51 – 53 %), 206 (23.5 – 27 %), 207 (20.5 – 23 %), and 204 (1.35 – 1.5 %). Variations in isotopic concentration can cause a difference of 0.15 in the normal atomic mass A_r of 207.21. Three of the natural isotopes are radioactive: ^{208}Pb is the end product of thorium decay, while ^{206}Pb and ^{207}Pb are formed from the uranium series via actinium and radium, respectively. A number of unstable radioactive isotopes exist with mass numbers of 200 – 203, 205, 209 – 214. Lead is a preferred shielding material against gamma rays and X-rays because of its high density and atomic number; if sufficiently pure, it does not become radioactive when used for shielding against neutron sources.

Physical and Mechanical Properties. The outstanding physical properties of lead are its low melting point, high density, softness, and malleability. The metal can readily be worked by rolling and extruding, and is slightly ductile. The physical and mechanical properties of lead follow:

Chemical Properties. Fresh cut or cast lead surfaces undergo oxidation and tarnish rapidly to form an insoluble protective layer of basic lead carbonate. Lead is attacked by water in the presence of oxygen, but again an insoluble carbonate or silicate protective layer is formed if dissolved carbonates or silicates are present in the water. This resistance of the metal to corrosion by air, water, and soil has been exploited in the historical uses of lead in plumbing and piping. Lead might be expected to dissolve in acids with liberation of hydrogen, but this is prevented by the high hydrogen overvoltage, and attack occurs only when the combination of oxidizing conditions and soluble salt species exists. Thus the metal resists hydrochloric acid corrosion to quite high concentrations, sulfuric acid to 60 °Bé (ca. 13.3 mol/L), and hydrofluoric acid totally; however, it dissolves readily in warm, dilute nitric acid to form soluble lead nitrate. Lead is also corroded by weak organic acids, such as acetic or tartaric acid, in the presence of oxygen. The protective coating formed by oxidation is removed by alkali with formation of soluble plumbites and plumbates.

Crystal Structure. Lead crystals are face-centered and cubic with the following dimensions:

Atomic radius, nm	0.175

Atoms per unit cell	4
Lattice constant (edge of unit cell), nm	0.49389

Electrochemical Properties. The electrochemical properties of lead follow:

Electrochemical equivalent, g A^{-1} h^{-1}	3.865

$Pb + 2\,OH^- \longrightarrow PbO + H_2O + 2\,e^-$	0.576
$Pb + 3\,OH^- \rightarrow HPbO_2^- + H_2O + 2\,e^-$	0.54

Lead forms two series of compounds corresponding to valence states of + 2 and + 4; lead (II) compounds are electrovalent (ionic), while those of lead (IV) are essentially covalent. The metal is amphoteric and forms lead salts, plumbites, and plumbates. When melted in air, lead oxidizes readily to its monoxide PbO (also called litharge or simply lead oxide); oxidation (drossing) can be promoted or inhibited by dissolved metallic impurities. Other lead oxides are the dioxide PbO_2 (actually sesquioxide Pb_2O_4) and red lead Pb_3O_4 (the orthoplumbate $Pb \cdot Pb_2O_4$). All the lead(III) halides are known, and are considerably more soluble in hot water than in cold; they also form double chlorides with alkali metals and a series of oxyhalides, the oxychlorides being the most familiar. Other common compounds of lead are the soluble nitrate and acetate; lead chromate (chrome yellow) used as a pigment along with red lead; lead borate used along with oxides in glass making; lead sulfide (galena), which is the principal naturally occurring form of the metal; and lead sulfate that is readily formed by sulfating a soluble lead salt and by natural oxidation of galena. Lead compounds are described in detail elswhere, ⟶ .

3. Occurrence

Charles A. Sutherland, Edward F. Milner, Albert Melin

Lead, like copper and zinc, is a markedly chalcophilic element. Its mean abundance in the Earth's crust is 16 g/t (0.0016 %). Enrichments occur only in the pneumatolytic and especially the hydrothermal sulfide phase in the form of vein (lode), impregnated, and particularly metasomatic deposits. Sedimentary enrichments are of little importance.

Lead Minerals. Galena or lead sulfide [1314-87-0], PbS, theoretically 86.6 % Pb, is by far the most important lead mineral and the sole primary one. Other common forms of naturally occurring lead are usually associated with or derived from galena deposits. They include mixed sulfides such as jamesonite, $Pb_4(Sb,Fe)_7S_{14}$ (ca. 40 % Pb) and boulangerite, $Pb_5Sb_4S_{11}$ (ca. 58 % Pb); anglesite, $PbSO_4$ (68.3 %) Pb), a product of galena oxidation; cerussite or white lead ore, $PbCO_3$ (77.5 % Pb), a decomposition product of galena; pyromorphite, also qualified as green, brown or variegated lead ore, $Pb_5(PO_4)_3Cl$ (76 % Pb); vanadinite, $Pb_5(VO_4)_3Cl$; wulfenite or yellow lead ore, $PbMoO_4$ (56 % Pb); crocoite, $PbCrO_4$; and phosgenite or horn lead, $Pb_2Cl_2CO_3$. Frequent impurities in lead minerals are zinc, copper, arsenic, tin, anitmony, silver, gold, and bismuth.

Deposits. The most important mineable lead ore is galena, which occurs chiefly in association with other minerals, mainly zinc ores. Lead deposits can be classified as follows:

1. Hydrothermal vein, impregnation, and replacement deposits (e.g., Broken Hill, Australia; Anvil Mine, Canada; and numerous deposits of the Cordilleran – Andean Orogeny);
2. Volcanogenic sedimentary deposits, some occurring as massive bodies of rich ore, others as impregnations (e.g., Sullivan Mine, Canada; Rammelsberg, Federal Republic of Germany; Mount Isa and Hellyer, Australia);
3. Hydrothermal or marine sedimentary deposits, typically in calcareous or dolomitic formations of the North American and European platforms (e.g., Pine Point, Canada; the New Lead Belt in the Missouri district, United States; Red Dog, Alaska).

In world mining output, mixed lead – zinc ore deposits are most important and account for ca. 70 % of total production of both metals. In second place are deposits that contain predominantly lead ores (ca. 20 % of total production), and the remainder (ca. 10 %) is obtained as a byproduct from zinc, copper – zinc, and other deposits.

An important byproduct of lead ore production is silver, which is incorporated into the lattice of galena, and is recovered with the lead when concentrates are smelted (⟶ Silver, Silver Compounds, and Silver Alloys). Some 70 % of world silver production comes from lead concentrates. Valuable amounts of gold are also contained in some lead deposits. Another byproduct from lead ore is copper, but the amount is a very small part of the total world copper output.

Reserves. Total world lead reserves were reported in 1987 as 75×10^6 t lead content (Table 1). Western countries owned about 73 % of the total.

Table 1. World lead ore reserves (millions of tonnes contained lead)

Country	Reserves [b]	Reserve base [c]
Australia	16	28
United States	11	22
Canada	8	15
Republic of South Africa	4	6
Mexico	3	4
Peru	2	3
former Yugoslavia	2	3
Other market economy countries	9	14
Centrally planned economies	20	30
Total	75	125

[a] U.S. Bureau of Mines, Division of Mineral Commodities, Jan. 1989.
[b] Estimated economically recoverable lead.
[c] Reserves augmented by marginally economic ores, some currently uneconomic but with potential, and also some provision made for determination of additional reserves in known ore bodies.

The United States has extensive lead deposits in the southeast of Missouri (New Lead Belt). These deposits and the new Red Dog lead – zinc orebody in Alaska are located in bedded marine-sedimentary or hydrothermal deposits. Further reserves are found in the Rocky Mountains (Idaho, Utah, Colorado) in the form of hydrothermal vein and replacement deposits. Canadian reserves are also substantial but of generally lower grade, and are located in the Appalachian region of New Brunswick, the Rocky Mountain trench, and the Yukon. North and South America, including the Latin American countries, hold about 35 % of known reserves.

Australia has the most substantial lead resources amounting to about 21 % of the world total; they are concentrated in Mount Isa (Queensland), Broken Hill (New South Wales), and Tasmania.

The remaining western reserves are found in many places in Europe, Africa, and Southern and Eastern Asia. The largest known European reserves are in former Yugoslavia.

Most Eastern Bloc reserves (ca. 27 % of world reserves) lie in the former Soviet Union (Kazakhstan and the Altai and Karatau regions). Only little information is available on these reserves and recent discoveries in the People's Republic of China.

Data on exploitable reserves are only valid in the short-term, because they are subject to long-term economic fluctuations. The growth of world reserves of lead ore through new discoveries can be expected to outstrip the increase in primary metal production. Recycling of lead, already a major source of the metal, particularly for battery making, can be expected to suppress production from primary sources.

[Top of Page]

4. Production

Charles A. Sutherland, Edward F. Milner, Albert Melin

4.1. Ore Concentration

The most common feed for lead production is sulfidic lead concentrate, which contains an average of 50 – 60 % lead (occasionally as high as 70 – 80 % or as low as 30 %). Oxide lead concentrates are of secondary importance.

Lead ores in deposits are usually intergrown with other minerals and with host rock. These crude ores are not smeltable and must first be beneficiated into concentrates of much higher lead content but with minimum loss of lead.

Ore beneficiation normally includes crushing, dense-medium separation, grinding, froth flotation, and drying of concentrate. Lead flotation is usually the first step in the separation of lead – zinc and lead – zinc – copper ores.

4.2. Smelting

The major process for the production of primary lead from a sulfide concentrate is the sinter oxidation – blast furnace reduction route. Older processes involving direct oxidation of lead sulfide to lead or the roast reaction between lead sulfide and the oxidation products lead oxide and lead sulfate are now of little importance. In the last two decades new oxygen

metallurgy processes featuring sulfide oxidation in a flash flame or by oxygen injection into a slag bath, followed by reduction of the lead oxide slag, have advanced to industrial application.

In the Imperial Smelting Furnace (ISF) process, lead is produced simultaneously with zinc. This process will not be considered here, for details see ⟶ Zinc.

4.2.1. *Sintering Reduction Process*

The sintering reduction process involves two steps: (1) a sintering oxidative roast to remove sulfur with production of PbO and (2) blast furnace reduction of the sinter product.

The objective of sintering lead concentrates is to remove as much sulfur as possible from the galena and the accompanying iron, zinc, and copper sulfides, while producing lump agglomerate of adequate strength combined with porosity for subsequent reduction in the blast furnace. The sulfur dioxide content of the sintering gases is often recovered and used in sulfuric acid production. The chemistry of the roast sintering process is complex because it involves many oxygen- and sulfur-containing lead compounds.

The Pb – S – O System. The Pb – S – O system was investigated comprehensively by KELLOGG and BASU [7] whose results were later confirmed by many investigators. WILLIS provides an excellent summary of the physical chemistry of the oxidation of lead sulfide [8]. Lead in sinter occurs mainly as lead monoxide or lead silicate. The temperature of the sinter charge must be high enough to attain the area of PbO predominance (i.e., > 950 °C, see Fig. 1).

Figure 1. Phase relations in the Pb – S – O ternary system with air as the oxidizer and a partial sulfur dioxide pressure of 0.2 atm [9]

* 1 atm = 0.1013 MPa

Oxidation starts with the formation of lead sulfate, which is the stable reaction product at the oxygen and sulfur dioxide partial pressures and temperatures commonly used in sintering. Lead sulfate then reacts further with lead sulfide, decomposing to increasingly basic sulfates and ultimately to lead monoxide. Lead in dust carried out by the sintering gas is totally sulfated.

The composition of the sinter is important as regards its behavior in the blast furnace. The lead monoxide and lead silicate which account for most of the lead content are readily fusible and reducible. The integrity of the sinter thus depends on the presence and quantity of other constituents, typically silicates of zinc, iron, and calcium, and ferrites. These substances are much more refractory than the lead compounds and provide a framework that keeps the sinter lump from disintegrating after the lead compounds have been removed.

Sinter Roasting Techniques. The development of sinter roasting goes back to work by HUNTINGTON and HEBERLEIN (1896), who proposed that lead ores mixed with limestone chips be roasted in a converter with an air blast (blast roasting). Implementation of this idea became the basis of the modern sintering technique, which combines roasting with agglomeration of the charge in the sintering step.

A continuous sintering machine with a sintering bell was devised in 1905 – 1908 by DWIGHT and LLOYD. At about the same time, VON SCHLIPPENBACH introduced the circular sintering machine.

A distinction is made between *downdraft sinter roasting*, where the air required for roasting is drawn downwards through the sinter mixture, and *updraft sintering*, in which the air is blown upwards through the bed. Updraft sintering is preferred because it produces lower gas volumes of higher sulfur dioxide content that are suitable for sulfuric acid production.

4.2.1.1. *Downdraft Sintering*

The original downdraft process proposed by DWIGHT and LLOYD was the conventional technique for the sinter roasting of lead ores until about 1955. It has now been superceded by updraft sintering. In downdraft sintering the nodulized charge blend is fed continuously onto a traveling grate, and sulfides are ignited on the surface of the charge bed by burners. As the ignited charge moves away from the ignition zone, air is drawn downward through the charge. The sulfur is burned on a downward advancing front, and incipient fusion of solids agglomerates the nodules of desulfurized charge into a porous sinter product.

A characteristic of downdraft sintering of lead ores is the low sulfur dioxide concentration of the roasting gases (Fig. 2). Since off-gases containing 1 – 2 vol % sulfur dioxide occur at the end of the sintering machine and cannot generally be discharged into the atmosphere, recirculation of the gas or chemical scrubbing is necessary. Even with gas recirculation, the production of acid-strength gas causes problems due to the formation of liquid phases during sintering that reduce the gas permeability of the bed, and in particular to the metallic lead formed by the reaction of lead sulfide with lead sulfate. The molten lead flows downward through the sinter bed along with the gas stream and forms a very tight layer immediately above the grate. Part of the lead also drops through the grate into the wind boxes. Removal of the lead from the wind boxes is expensive and causes long downtimes. Water-bath quenching of wind-box lead and conveyor belt cleaning have been practised to overcome this problem. With downdraft sintering the maximum lead content of the sinter mix is limited to about 40 % to avoid excessive production of wind-box lead.

Figure 2. Variation in sulfur dioxide content of sintering gases along a downdraft sintering machine

4.2.1.2. *Updraft Sintering*

Principles. The difficulties encountered in downdraft sintering are avoided in updraft sintering in which sintering takes place in an ascending gas stream (Fig. 3). Roasting air is supplied to the machine from below through the wind boxes, and the gas flows upward through the sinter bed. To initiate roasting, a 2 – 3 cm layer of feed is placed on the grate and ignited in a downdraft ignition box (Fig. 3 A). The main sinter bed (d) is then distributed onto the burning ignition layer (b), the direction of gas flow is reversed (Fig. 3 B), and air is forced upward through the sinter bed. The main layer is ignited from the first layer, and sinter roasting advances upward. To prevent caking of the ignition layer on the grate bars during downdraft ignition, the grate is usually covered with a hearth layer of return sinter (c) before the ignition layer is placed.

Figure 3. Updraft sintering

A) Downdraft ignition; B) Sinteringa) Ignition hood; b) Ignition layer; c) Hearth layer; d) Sinter bed; e) Exhaust hood

Since cold air flows into the sinter bed from below, any metallic lead that forms is immediately cooled and solidifies while still in the bed. This makes for good permeability of the bed, lower gas flow, and uniform sintering. Higher sulfur dioxide levels in the roast gases can thus be achieved, and sinter charges containing up to 50 % lead can be managed.

Plant Design. The development of updraft sintering began in 1950 – 1955 at the Port Pirie lead smelter in Australia and at Lurgi Gesellschaft für Chemie und Hüttenwesen, Federal Republic of Germany. The process has since been adopted worldwide. All constructed sintering plants have been designed for updraft sintering and a large number of downdraft plants have been reconstructed. Updraft sintering became an essential component of the Imperial Smelting zinc process because of the exacting requirements for satisfactory operation (i.e., low sulfur and high sinter hardness).

The flowsheet of a plant of modern design is shown in Figure 4. Developments have concerned not only increases in the size of updraft sintering machines, but also improvements in capacity, automation, and of working conditions. Dust-collection systems and gas-cleaning systems must comply with increasingly strict regulations on air and water pollution control.

Figure 4. Flowsheet of an updraft sinter plant for lead ores

An updraft sintering plant comprises many devices and machines, which employ a logical system of electrical interfaces. Precise control of process performance is difficult, primarily because lag times from entry of the feed to appearance of the product from the sinter strand are long and sampling of the feed and product sinter are difficult. Consistent feed preparation, either by means of large-scale bedding operations or very accurate weigh feeders for the concentrates and fluxes, can provide a high precision of feed-forward control.

Feed Mixture. A charge moisture content of 4.5 – 5.5 % is of utmost importance for achieving good bed permeability during combustion. The desired moisture content of the feed mixture is attained by adding water to the tumbling and mixing drum. Two drums usually operate continuously to achieve good control. If feed material moisture is too high, charge drying is required.

Crushed recycle sinter is required to control the fuel content of the charge and to enhance bed permeability. Cooling of recycle sinter is necessary for mechanical reasons and to minimize dust production. The main difficulties encountered in return sinter cooling are caused by irregular discharge of the sinter strand combined with the handling of moist ventilation gases produced in water quench cooling drums.

Because sinter quality and plant capacity are strongly affected by the physical quality of the recycled sinter, comminution of the returns is very important. The desired size distribution of the lump sinter that is to be reduced in the blast furnace is obtained by two-stage crushing and screening. The returns needed for the sinter charge are also broken down to the requisite particle size (normally 6 mm) by using roll crushers in a two-stage process.

Dust Collection. Dust collection is a major problem in updraft sintering plants. The plant comprises many machines and devices, some of which must transport, screen, and crush hot material; lead-containing dust is produced at all transfer points. Proper ventilation is essential to provide satisfactory in-plant hygiene, and efficient cleaning of exhaust gas is required to

control lead emissions. High volumes of ventilation air have to be handled at considerable extra cost. Dust recovered from baghouses and wet scrubbers must be recycled to the process.

Because sintering plants emit both dry and wet dust-laden gases, gas cleaning design has been constantly improved. For a detailed description of dust collection see ⟶ Dust Separation. The most recent plants employ a combination of wet scrubbing and dry baghouse gas cleaning. The cooling drum ventilation and the hot gases from the sintering machine are cleaned in water scrubbers. Discharge gas temperatures are too high for bag filters. The other dust-collection points (crushing and screening) are combined in a common baghouse. Dust recovered from baghouses is added to the thickener slime that is supplied as coolant to the cooling drum. The dust load in the process sulfur dioxide from the sintering machine is usually collected in high-temperature electrostatic precipitators, moistened, and added directly to the sinter mixture.

Recovery of Sulfur. For optimal operation of the sintering machine, some 15 – 20 $m^3\ m^{-2}\ min^{-1}$ of air (at STP) must be delivered along its whole length. The combined exhaust gases have an average sulfur dioxide content of 4 – 5 vol %. However, since peak sulfur dioxide levels of over 10 % occur at the front end of the sintering machine, a rich gas stream with a relatively high sulfur dioxide content can be separated and the balance tail gas is recycled to the front-end wind boxes. In this way, a rich gas containing 6 – 6.5 vol % sulfur dioxide can be delivered to a sulfuric acid plant. The technique involves a certain deliberate loss of capacity resulting from the injection of hot recycled lean gas at 300 – 350 °C.

Size and Capacity of Sintering Plant. Standard sizes have been adopted for updraft sintering machines. Size is defined chiefly by smelting capacity and by the quantity of sulfur to be combusted.

Roasting capacities of 1.3 – 1.5 t $d^{-1}\ m^{-2}$ are achieved with modern updraft sintering and are over 50 % higher than those of older downdraft systems. For normal lead sintering an annual lead production capacity of 70 000 – 100 000 t requires a sinter machine of 50 – 70 m^2 updraft area. Machines up to 90 m^2 are employed in Imperial Smelting process plants. These rates and sizes are material-dependent and must be confirmed by tests for each proposed charge. Data for the updraft sinter plant at Port Pirie, Australia are listed below:

Number of sinter machines	1
Roasting surface	
total, m^2	70.5
effective, m^2	62.3

Sintering for the Imperial Smelting Process. Lead – zinc concentrates or mixtures of lead and zinc concentrates for the Imperial Smelting Furnace (ISF) process must be desulfurized and sintered before reduction in the zinc vaporizing blast furnace. The sinter must incorporate recycled intermediate products from the sinter plant and blast furnace and also the fluxes needed to obtain the desired slag balance. The sinter must be chemically uniform, well desulfurized, as well as hard and abrasion-resistant to avoid formation of fines in the furnace. It must also have a high porosity and a narrow particle-size range.

These requirements can be satisfied only by carefully controlled updraft sintering with feed sulfur held between 5 and 6.5 %, moisture at 4 – 7 % and return sinter sizing between 1 and 5 mm. For further details, see ⟶ Zinc.

4.2.1.3. *Products of Sinter Roasting*

Sinter. Product sinter should be agglomerated in large lumps that are strong enough to prevent decrepitation during handling. The sinter should have a cellular, porous structure without pockets of unroasted ore or very dense regions.

Sintering Gases. The sulfur dioxide concentration in the sintering gases is lower than that found in the roasting of zinc or copper ores, especially when high-lead concentrates containing as little as 14 – 16 % sulfur are processed. In the sintering of lead concentrates, the sulfur dioxide level fluctuates between 4 and 6 vol % under favorable conditions and with gas recycling. Release of the lean gases into the atmosphere is unacceptable, although this is still done in a few instances. The roasting gases contain a small amount of sulfur trioxide; their dust content is usually 2 – 5 g/m^3, but may reach 20 g/m^3 in exceptional cases. Extensive cleaning is always necessary if the gas is to be processed into sulfuric acid. Pollution control laws require that metal losses be kept to a minimum. The typical gas cleaning train consists of dry electrostatic precipitators, a wet scrubber, followed by wet electrostatic cleaning.

The cleaned sintering gases are generally forwarded to sulfuric acid production. They are sometimes processed into liquid sulfur dioxide after absorption in an organic solvent. In rare cases they are scrubbed with ammonia to produce ammonium sulfate and high-strength sulfur dioxide for recycle or liquid sulfur dioxide production.

Sulfuric acid derived from lead-sintering plants is produced as " black acid ". Its black color is due to carbon particles from the volatile organic constituents of flotation reagents. The color can be removed with hydrogen peroxide at additional expense.

Flue Dusts. Flue dusts from lead sintering plants contain 60 – 70 % lead, about 10 % sulfur, and varying amounts of zinc, cadmium, arsenic, antimony, and mercury. The lead is predominantly in the form of lead sulfate or basic lead sulfate, with a minor quantity of lead sulfide. Flue dusts are recycled to the sinter blend.

4.2.2. *Reduction in the Blast Furnace*

The second part of the roast – reduction process is carried out in a blast furnace. Where the lead content of the sinter (mainly lead oxide) is reduced to metallic lead, other metals such as copper, antimony, arsenic, and noble metals are also produced. Other constituents (*gangues*) contained in the sinter and the flux are carried off as silicate slag. In lead blast-furnace smelting, zinc remains in the slag, but in the Imperial Smelting process the furnace top is hot and gaseous zinc leaves the furnace along with the off-gases and is then condensed to liquid zinc metal.

The charge to the blast furnace comprises

1. Sinter, which incorporates the roasted concentrate and fluxes
2. Other oxygen-containing lead materials such as oxides and silicates
3. Metallurgical lump coke as the reducing and heating fuel

4.2.2.1. *Process Description*

The lead blast furnace is a countercurrent reactor in which a charge (sinter and coke) moves through a vertical shaft in countercurrent to the ascending gas flow. The descending charge successively passes through the preheating zone (to ca. 200 °C), the reaction or reduction zone (to ca. 900 °C), the melting zone (to ca. 1150 °C), and finally the combustion zone (tuyere zone). The liquid reaction products collect in the furnace crucible, which is located below the tuyere zone.

Principles. In the combustion zone, atmospheric oxygen blown in through the tuyeres reacts with the coke to form carbon dioxide with extensive release of heat. This hot gas ascends through a coke-rich layer (arch) and is reduced to carbon monoxide, the main reductant. In the melting zone and in the overlying reduction zone, heat is transferred from the gas and liquid slag is formed from the fluxes and sinter gangue. Most of the metal-forming reactions take place in the softening-melting zone, even though the residence time in this zone is relatively short. Before fusion, heterogeneous gas – solid reactions and heat transfer processes take place. Free moisture and water of crystallization are driven off in the preheating zone.

The rates of coke combustion and conversion of carbon dioxide to carbon monoxide (Boudouard reaction equilibrium) must

be in accordance with the rate of reduction in the reaction zone and with the rate of heat transfer. If the combustion rate exceeds the rate of heat transfer to the charge, the coke burns more rapidly than the charge melts causing the melting zone to rise in the furnace. If the combustion rate is lower than the rate of heat transfer, the coke burns so slowly that it prevents the charge from descending and slows down the performance of the furnace. If the rates of combustion and heat transport are in good agreement, the melting zone and thus the plastic region are narrow. The charge material then flows through at a uniform speed and gas channeling and blow holes are minimized.

For optimal heat and mass transport in the reaction zone, gas velocity should be high and the resistance to gas flow low. The physical and chemical characteristics of the sinter should ensure adequate solids integrity in the reaction zone. Finally, the blast furnace charge should be as physically homogeneous as possible.

Behavior of Sinter Components. The exothermic reduction of lead oxide by carbon, carbon monoxide, and hydrogen begins at relatively low temperature. Other oxygen-containing lead species (e.g., aluminates, silicates, and ferrites) require more intense reducing conditions. Lead sulfate and the basic lead sulfates are converted chiefly by reaction with silicates, but they can also react with sulfides to yield metallic lead. Lead sulfide partly reacts with sulfates to form metallic lead.

The noble metals are largely dissolved in the lead product (*bullion*), with small amounts distributed to sulfide matte and slag.

The copper content of the sinter is captured in the matte in sulfide form, provided sufficient sulfur is present. If, however, the sulfur level is insufficient, the copper is reduced and goes into solution in the lead bullion. A small portion of the copper is always incorporated into the slag in either oxide or sulfide form.

Zinc oxide is located in the slag, and to keep it in solution the slag must be rich in iron(II) oxide. Zinc levels in slag exceeding 18 – 20 % cause slag viscosity problems and some hearth accretions. Part of the zinc oxide is reduced to zinc vapor above the tuyere zone, but the vapor is immediately reoxidized to zinc oxide in the colder zone (zinc circulation in the blast furnace). Zinc sulfide, charged in the sinter or formed from metallic zinc, is notorious because it promotes the formation of accretions on the walls of the smelting shaft. If a matte is formed, it can dissolve a certain amount of the zinc sulfide, but then its melting point rises and the physical separation of the slag becomes more difficult.

Antimony and arsenic compounds are reduced to the respective metals which dissolve in the lead bullion. If the amount of arsenic is too large to be absorbed by the matte, and if copper, iron, and nickel are also present, metal arsenides (*speisses*) may be formed. Some arsenic is also volatilized and some is slagged. Tin is partly reduced into the lead bullion.

Separation of the fused products leaving the furnace hearth is based on their low mutual solubility and their differing densities (lead bullion about 10.5, matte 4.5 – 5.0, slag 3.5 – 3.8 g/cm^3).

4.2.2.2. *Lead Blast Furnaces*

Lead blast furnaces are classed in two groups: round (*mushroom furnaces*) and rectangular (*Rachette furnaces*). The round design is only used in special low-capacity operations. The Rachette furnace is the standard type of lead blast furnace, and often has rounded corners. The *chair-jacket furnace* is a modification of the Rachette design and has two rows of tuyeres, one above the other. Figure 5 shows two conventional blast-furnace profiles.

Figure 5. Blast furnace profiles

A) Single-level tuyere furnace; B) Double-level tuyere furnacea) Upper shaft (preheating); b) Lower shaft (melting, reduction, tuyere zone); c) Crucible (slag, lead); d) Shaft and tuyere water jackets; e) Blast air bustle pipe; f) Blast tuyeres

A typical lead blast furnace has a rectangular cross section 5 – 8.5 m above the tuyeres, a water-cooled melting zone, and a syphon tapper for continuous lead discharge. For a given charge, furnace capacity can be increased only by enlarging the cross section. The area of the tuyere zone is the controlling factor. The world's largest furnace, employed by the Broken Hill Associated Smelters, Port Pirie, Australia, has a tuyere zone length of 10 m. Structural and operating data for this furnace are listed below:

Number of furnaces	1
Type	Rachette type with chair jackets

Top gases, m^3 m^{-2} min^{-1} (STP)	16.2
Type of lead tapper	Asarco – Roy

The tuyere zone width can be increased only as long as the blast can penetrate from both sides, generally to around 1.5 m. The furnace can be widened if two offset rows of tuyeres are placed one above the other such that the center (“ dead zone ”) of the charge is brought to the melting point in the narrower bottom tuyere zone. Since the penetration depth of the blast in the furnace permits a maximum width of 1.8 m in the bottom tuyere zone, the top tuyere zone has a maximum width of 3.6 m. Widths of 1.5 and 3 m have been achieved in practice. The cooling jackets have the shape of a chair, which gives this configuration its name (see Fig. 5 B).

The furnace shaft was formerly constructed of refractory bricks, but in modern furnaces a series of supported water jackets form the shaft, which may be either vertical (Fig. 5 B) or taper toward the bottom (Fig. 5 A). The hearth is subjected to the highest temperature and is cooled by one or more rows of replaceable cooling jackets set one on top of another.

The jackets are cooled with water that is either pumped in a closed cycle or circulated by the thermosiphon principle (i.e., natural convection). Jacket cooling by evaporative cooling (steam generation) is practised in the former Soviet Union. The water jackets have openings for the tuyeres through which the blast enters. Combustion air must be at a pressure between 5 and 20 kPa. The resistance of the furnace depends not only on the quantity of blast injected but also on the permeability of the charge. Blowers whose delivery is variable but independent of the furnace back-pressure are most suitable. These requirements are best met by positive blowers with a variable speed, but equipment wear often dictates their replacement by centrifugal blowers.

Tests at several lead smelters have demonstrated that enrichment of the blast with oxygen increases throughput (ca. 5 % increase for each additional 1 % oxygen in the blast). When oxygen replaces part of the blast air, a higher combustion zone temperature is achieved, gas flow per unit of lead is reduced, and the furnace operates more smoothly. Benefits include increased production, a reduction in coke consumption, lower off-gas temperatures, and lower dust generation. Similar results have been achieved with preheated blast air. Whether oxygen enrichment or blast preheating is preferable depends only on economics. Oxygen enrichment has become more popular, especially since low-cost oxygen production has become increasingly common. However, as yet the degree of enrichment of the lead furnace blast is very modest: only 2 – 3 %.

A crucible located below the tuyeres serves to separate the liquid products and collect the lead. In large production units, lead is withdrawn continuously, and in smaller ones tapped at intervals. If the lead bullion has a high copper content, the continuous syphon tapper runs into accretion problems. It should be replaced by a discontinuous tapper placed just above the bottom of the crucible, so that it is always covered with molten lead to protect it against deposits. With the Asarco (Roy) continuous tapper the liquid phases are separated outside the furnace [10]. Lead and slag are discharged together into an external settler attached to the furnace, in which the liquid phases are separated. The Asarco tapper gives higher capacities with lower investment and maintenance costs, along with more hygienic workplace conditions. It has the drawback of a higher lead level in the slag. North American smelters employ the Asarco tapper; some European smelters use the Arents syphon tapper.

If a separate matte phase is formed, slag and matte can be separated in a heated launder, where the matte with its higher relative density settles and the slag floats. If the slag is to be discarded or kilned for zinc recovery, it is usually granulated. It may, however, also be transported in the molten state to a zinc fuming furnace.

The charging of blast furnaces is largely automated. Charging devices for open-top furnaces may be bucket elevators and skips or a variable discharge conveyor belt. Tipping or bottom dump charge buckets are used for the more common closed-top furnaces. Various alternating charging techniques are employed to achieve layers or blends of coke and sinter in the shaft. Blast-furnace top gases are drawn off the furnace top by an exhaust fan and passed through a baghouse for dust

removal.

4.2.2.3. *Products of the Lead Blast Furnace*

The lead blast furnace yields the following products:

1. *Lead bullion,* which must be further refined (see Chap. Refining of Lead Bullion).
2. *Slag*, which may contain large amounts of zinc and must then be further processed.
3. *Flue dusts and baghouse dusts,* which consist of fumes and dust particles carried over by the furnace top gases. Cadmium tends to accumulate in this dust, and sometimes a special cadmium separation leach is carried out before the dust is recycled to sintering.
4. *Top gas.* Blast furnace top gas usually contains 3 – 4 % carbon monoxide, which represents an unavoidable energy loss. With normal heat exchange between gas and solids in the shaft the top gas is too cold for practical heat recovery, so after dust removal it is released to atmosphere.
5. *Matte,* a sulfidic product of blast-furnace smelting, forms only if the burden contains enough sulfur. In general, provided the charge does not contain too much copper or sulfur, matte phase formation is avoided with the copper remaining in solution in the lead bullion and slag. Subsequent reverberatory melting of lead bullion drosses yields copper matte, lead metal, and slag. The copper matte can contain varying amounts of lead, iron, zinc, and noble metals. Copper matte is usually sold to special copper smelters, but processing of matte to copper sulfate or copper metal is becoming more common.
6. *Speiss* is only formed when the burden contains amounts of arsenic, nickel, cobalt, and antimony that are so large that they can no longer be taken up by the matte. Speiss is undesirable, because it dissolves large quantities of noble metals and also requires expensive refining.

Composition and Processing of Slag. The slag consists of gangue, fluxes, and the zinc contained in the charge. It also contains dissolved and suspended metals (lead, copper, silver), which are a potential economic loss. The chemical and physical properties of the slag have a considerable effect on furnace throughput, product separation, metal recovery, and coke consumption in the furnace. Lead blast furnace slag should have a low melting point, be adequately fluid (low viscosity) at the furnace bottom temperature [11], and have minimal density. Slags are compounded to attain these properties by fluxing to selected component ratios. Thus, in the ternary system CaO – FeO – SiO_2 almost all lead blast furnace slag compositions lie in an area that is bounded by weight ratios of 1 : 1 to 4 : 1 for SiO_2: CaO and 1 : 2 to 3 : 2 for SiO_2: FeO (Fig. 6). This is further illustrated in Figure 7 for a number of North American and Australian lead blast furnaces.

Figure 6. The FeO – SiO_2 – CaO ternary system, showing compositions of several lead blast furnace slags (•) [12]

Figure 7. SiO_2 : FeO and SiO_2: CaO weight percentage ratios in blast furnace slags [13]

a) Asarco, East Helena; b) Asarco, El Paso; c) Asarco Glover; d) Amax; e) Brunswick M & S; f) Cominco; g) Mount Isa; h) BHAS, Port Pine; i) St. Joe Lead

Lead blast-furnace slag often contains sufficient zinc to make recovery profitable by rotary kiln or submerged combustion slag fuming. In both cases zinc oxide in the slag is reduced to metallic zinc (vapor) by carbon, oxidized by secondary air, and carried out in the furnace gases for recovery of zinc oxide dust.

Zinc recovery rotary kilns (Waelz kilns) are up to 95 m long with an internal diameter of up to 4.5 m and they are lined with refractory material. The granulated blast-furnace slag is mixed with other zinc intermediates (steel dusts, etc.) and solid fuel reductant; it travels down the kiln and is heated to reaction temperature by combustion gases from a burner at the discharge end. The stripped slag is usually close to its melting point at discharge, and normally contains 2 – 3 % zinc and <0.25 % lead. Production from a Waelz kiln is about 120 – 155 kg of zinc per day per cubic meter of furnace volume, declining with increasing furnace size. The captured dust contains roughly 75 % zinc and lead. Zinc recovery is 88 – 95 % and lead recovery is about 90 – 98 %.

In the *slag-fuming process* a mixture of coal dust and air is injected through tuyeres into a liquid blast-furnace slag at 1150 – 1250 °C in a water-jacketed furnace. The slag is delivered in liquid form directly from the lead blast furnace and may have up to 30 % of solid granulated slag or slag skulls added to it. The process is typically operated in batch mode in furnaces of 50 – 100 t capacity.

At the Plovdiv lead smelter in Bulgaria, slag is tapped continuously from the lead blast furnace through a slag syphon. It then flows through a preheating electric furnace (+ 100 °C) and enters the continuous slag fuming furnace. Heavy fuel oil is used as reductant rather than the more conventional pulverized coal.

Metal recoveries in slag fuming plants are about the same as in Waelz kilns. Slag fuming furnaces normally recover heat from the hot gases in waste heat boilers or air heat exchangers.

4.2.2.4. *Imperial Smelting Process*

In the Imperial Smelting process, lead and zinc are produced together in a single blast furnace operation. This is basically a zinc production process in which lead is also obtained. It is especially well-suited to processing lead – zinc mixed concentrates. The zinc to lead ratio in the sinter mixture is usually 2 : 1. The furnace design is similar to that of conventional lead blast furnaces of the chair-jacket type, but there is only one row of tuyeres. The top is closed by a double-bell system. For process principles and description, see ⟶ Zinc.

4.3. Roast Reaction Processes

Lead sulfide reacts with lead oxide or lead sulfate to form metallic lead and sulfur dioxide in the *roast reaction*:

$$PbS + 2\,PbO \rightarrow 3\,Pb + SO_2$$

$$PbS + PbSO_4 \rightarrow 2\,Pb + 2\,SO_2$$

A number of processes dating from the earliest times have been used to recover lead by partial air oxidation of lead sulfide. These processes are categorized as excess sulfur or excess oxygen, depending on whether the reaction series exhausts the oxide and sulfate or the sulfide species, respectively. High-grade lead concentrates are required in order to maximize the activities of the lead species and, therefore, lead recovery.

The principal commercial example of the excess sulfur type is the *Boliden electric furnace process.* Since this process contains elements of flash smelting, it is described in Section Direct Smelting Reduction Processes.

An example of the excess oxygen roast reaction chemistry is the *Scotch (Newnham) hearth process,* one of the earliest lead-making techniques. The old furnace design was improved and automated in the Bleiberger Bergwerks Union (Schlippenbach) rotary hearth [14]. This process produces a small quantity of high-lead (grey) slag which requires separate recovery treatment, and low-strength sulfur dioxide gas, unsuitable for production of sulfuric acid. The hearth processes are now antiquated and are responsible for a very small amount of lead production.

4.4. Direct Smelting Reduction Processes

The fundamental problems encountered in the sinter, oxidation – blast furnace method of lead production (e.g., high process and hygiene ventilation gas volumes, high maintenance costs for sintering machinery, and expensive coke fuel for reduction) have long been recognized. The quest for a simpler, more direct smelting system has been pursued for many years, and several new processes have now achieved industrial application.

Table 2 summarizes the key features of the most prominent new lead smelting processes. They can be classified into two principal categories: *flash smelting* of dried feed mixtures using air or oxygen, and *bath smelting* of undried feed mixtures also with air or oxygen. Oxidation of the feed produces a medium-strength sulfur dioxide gas, a variable amount of lead bullion, a slag rich in lead monoxide, and a lead sulfate flue dust which must be recirculated.

Table 2. Summary of direct smelting lead processes

Process	Smelting type	Source of oxygen	Special features
Boliden Electric furnace	dry charge flash smelting continuous	enriched air	flash oxidation in freeboard of electric furnace; slag reduction by coke breeze in electric furnace; lead bullion is high in sulfur requiring special treatment
Kivcet	dry charge flash smelting continuous	technical oxygen	an electric furnace freeboard is separated into an oxidation flash smelting shaft and a slag reduction section by a partition wall extending into the slag bath; majority of slag reduction is done by coke checker at bottom of smelting shaft
Boliden Kaldo	batch dry charge flash smelting into TBRC vessel	technical oxygen	batch oxidation is followed by slag reduction in same vessel using PbS followed by coke reductant
Outokumpu	dry charge flash smelting continuous	technical oxygen	slag reduction done in separate electric furnace employing powdered coal injection with nitrogen through lance
Isa Smelt	moist charge slag bath smelting continuous	air or enriched air	air is injected into slag batch by Sirosmelt lance; feed dropped into slag bath; slag reduction by coal in a similar lance-vessel unit
QSL	moist charge slag bath smelting continuous	technical oxygen	horizontal cylindrical reactor divided into oxidation and reduction sections by refractory wall; oxygen injected into lead-slag bath through nitrogen shrouded tuyeres; moist feed dropped into slag bath; slag reduction by submerged combustion of oxygen fuel in gas shrouded tuyeres

The strength of the sulfur dioxide gas produced depends on the degree of oxygen enrichment and the amount of auxiliary fuel required for autogenous operation of the oxidation step. With the use of oxygen, sulfur dioxide gas contents of 20 – 30 % are typical.

The amount of direct-smelt lead bullion produced during the oxidation step depends on the thermal balance. In the case of direct smelting of a very high-grade lead concentrate, up to 80 % of the lead in the charge can be obtained as direct bullion with the remaining 20 % as a slag rich in lead monoxide. With low-grade feed charges requiring auxiliary fuel, all lead can be oxidized to a high-lead slag, with no direct bullion production.

The second step in direct smelting processes is reduction of lead from the high-lead slag (25 –40 % Pb). Slag has been successfully reduced by submerged fuel combustion or injection, reduction assisted by an electric furnace, and a combination of these techniques.

4.4.1. *Air Flash Smelting*

Boliden Process [15]. Dry, high-grade galena concentrate (65 – 75 % Pb) is blown into an electric furnace with oxygen-enriched air. Limestone flux and coke breeze are also included in the feed charge. Suspended lead sulfide particles react to produce lead monoxide and lead metal, which collect in the furnace hearth along with the fused slag constituents. Desulfurization is not complete. The furnace products are lead bullion containing 2 – 3 % sulfur, slag containing 4 – 5 % lead, and flue dust. Desulfurization of bullion is completed by air blowing in a downstream converter.

The Boliden electric furnace process has operated successfully since 1963 at the Ronnskar Smelter in Skelleftehamn, Sweden. The 8000-kVA smelting furnace employs four Söderberg electrodes. Product slag is treated in a slag fuming furnace (see Section Products of the Lead Blast Furnace) along with copper slag for zinc and lead recovery. A section of the electric furnace is shown in Figure 8 and typical daily furnace charge and production figures are listed below:

Charge	
concentrate	280 t
limestone	40 t
iron oxide	7 t
coke breeze	7 t
recycle flue dust	140 t
drosses	15 t
oxygen enrichment	25 % O_2
Products	
slag	70 t (34 % CaO, 17 % Zn)
bullion	280 t

Figure 8. Boliden lead smelting electric furnace

a) Dryfeed hoppers; b) Dry feed-air injection ports; c) Söderberg electrodes; d) Slag bath; e) Lead bullion

Several drawbacks have prevented wider industrial application—high-grade lead concentrate is required, flue dust production is high, and bullion treatment is required to remove residual sulfur.

4.4.2. *Oxygen Flash Smelting*

The most prominent oxygen flash smelting processes for lead production are the Kivcet CS process developed in the former Soviet Union [16], the Kaldo process developed by Boliden in Sweden [17], and the Outokumpu process developed in Finland [18]. In all these processes, very complete desulfurization of the charge is effected through the production of a strongly oxidizing slag. The required oxygen potential can only be achieved with lead monoxide when its weight fraction is high (>35 % lead in the initial slag) [19]. The other major slag components are in ratios very similar to those found in blast-furnace slag.

4.4.2.1. *Kivcet Process*

The Kivcet process was developed at the Vniitsvetmet Institute, Ust Kamenogorsk, the former Soviet Union. Of the developed smelting processes, the Kivcet process is the most advanced, with industrial plants operating at the Ust Kamenogorsk Lead – Zinc Combine and at the Samim lead – zinc metallurgical complex in Portovesme, Sardinia. The Kivcet furnace at the Samim plant is a sophisticated structure, employing extensive water-cooling on the furnace side walls and in the smelting shaft. The general process flows are shown in Figure 9. Figure 10 shows a section of the smelting furnace at

Portovesme.

Figure 9. Kivcet lead smelting process

Figure 10. Kivcet lead smelting furnace (Portovesme, Italy)

a) Oxygen burner for dry feed; b) Flash smelting shaft; c) Furnace electrodes; d) Partition wall; e) Membrane wall SO_2 gas cooler; f) Slag bath; g) Lead bullion; h) Zinc fume combustor – cooler; i) PbO reduction coke layer

As shown in Figure 10, the oxidation section of the electric furnace freeboard is separated from the reduction section by a water-cooled, gastight wall (d) which dips into the furnace slag bath. Dried and blended charge components consisting of lead concentrate and other lead-bearing materials, required fluxes, recycle flue dust, and oxygen are fed through burners (a) at the top of the oxidation shaft (b). Combustion of charge constituents at a temperature up to 1400 °C and a shaft height of 3 – 5 m permits almost complete desulfurization before collection of the reaction products in the slag bath (f).

Reduction of the lead monoxide from charge combustion is accomplished mainly by using a layer of coke particles floating on the slag bath under the combustion shaft. The coke particles are also a component of the burner feed. Reduced slag and lead bullion flow under the submerged partition wall (d) into the reduction section of the electric furnace where reduction of lead monoxide is completed to produce a slag containing 2 – 3 % lead. If desired, additional coke breeze reductant and electrical energy can be used to fume zinc. In this mode of operation, product slag containing 3 – 4 % zinc and 1 – 2 % lead can be obtained. Zinc fumed in the electric furnace can theoretically be recovered as metal using a lead splash condenser, but a simpler approach is to burn the zinc vapor to zinc oxide in a combustion flue (h) and recover an oxidized flue dust for further zinc recovery processing.

Lead bullion is removed from the furnace by a syphon and slag is withdrawn continuously from a weir overflow.

Sulfur dioxide gas from the combustion shaft passes under a water-cooled partition wall before rising in an extended vertical wall boiler duct. Cooling of the sulfur dioxide gas – flue dust mixture to 450 °C is accomplished in the vertical boiler stack (e) before the gases enter an electrostatic precipitator for separation of the lead sulfate fumes. Flue dust production is moderate, about 10 – 20 % of the feed charge weight.

The Kivcet process can smelt oxidic charge materials such as zinc leach residues. Extra auxiliary fuel for adequate flame temperature and sufficient shaft height for adequate retention time must be provided to achieve the required degree of desulfurization.

4.4.2.2. *Boliden Kaldo Process*

The Boliden Kaldo process employs a top-blown rotary converter in a batch manner. A cycle starts with oxygen combustion of dry charge constituents into a preheated empty vessel. Figure 11shows the process flows. Charge combustion is continued until lead bullion and high-lead slag have accumulated to the limit of vessel weight or volume capacity. Charge combustion is then stopped and slag reduction commences. Lead sulfide concentrate is used to reduce a major portion of the lead monoxide in the slag, followed by coke breeze reduction to discharge slag composition. The vessel's slag and bullion contents are then poured into ladles, and the smelting cycle repeated.

Figure 11. Boliden Kaldo process

a) Feed drying; b) Kaldo vessel; c) Gas cooling and cleaning

The Boliden Kaldo process can handle a variety of lead-containing charge materials such as secondary scrap and flue dusts. The cyclic production of sulfur dioxide – bearing gas and barren reduction gas introduces some complications to the gas handling and sulfur dioxide recovery system.

4.4.2.3. *Outokumpu Process*

Outokumpu Oy of Finland pioneered the air flash smelting of copper concentrates in the late 1940s, and this process has become standard worldwide. Experimental work on air flash smelting of lead concentrate in pilot plants was carried out in the 1960s. Little commercial interest was shown at that time, and pilot-plant testing on several types of lead concentrates was not resumed until the late 1970s, when oxygen rather than air was used for the flash smelt. Full-scale lead smelter

engineering studies have been carried out, but to date no production plants have been constructed.

The process scheme of the Outokumpu lead flash smelting process is shown in Figure 12. Lead concentrate and flux are dried in a rotary dryer (a), mixed with recycle flue dust, and then flash smelted with oxygen in the oxidation furnace smelting shaft (b). High-lead slag and lead bullion collected in the furnace hearth may be tapped separately to provide a direct lead bullion product. Alternatively, if direct lead bullion production is small, slag and bullion are tapped together into a separate electric slag reduction furnace (d). In the electric furnace, pulverized coal is injected with nitrogen into the slag bath to reduce lead monoxide.

Figure 12. Outokumpu lead smelting process

a) Feed drying; b) Flash smelting furnace; c) SO_2 gas cooling and cleaning; d) Electric slag reduction furnace; e) Electric furnace gas cleaning

The pilot-plant equipment consisted of a rotary dryer, dry concentrate bins, pneumatic conveyors for concentrate and recycle flue dust, a flash furnace (15 m^3), a waste heat boiler (3 t/h steam), an electrostatic precipitator, and a 2 MVA electric furnace.

The pilot plant processed 3 – 5 t/h of concentrate ranging from 47 % to 75 % lead content. Bullion and slag were continuously tapped to the electric furnace for slag reduction. About 10 000 t of lead concentrate were processed.

4.4.3. *Air – Slag Bath Smelting, the Isasmelt Process*

The Isasmelt process (Fig. 13) consists of two stages and was developed by Mount Isa Mines and Csiro in Australia [20]. Both stages, the charge oxidation stage and the slag reduction stage, employ a stationary, cylindrical, refractory-lined reaction vessel. The process features the Sirosmelt lance, which is a steel pipe that is cooled by the high-velocity process air which it injects into the melt. In the oxidation vessel (b), air or oxygen-enriched air and supplementary oil fuel are injected through a Sirosmelt lance (c) into the center of the vessel. The blended feed materials (d), lead concentrate, fluxes, and moist recycle flue dust are dropped into the slag bath and agitated by the lance burner. Virtually all the charge lead content is oxidized to a high-lead monoxide slag. The slag is transferred to the reduction vessel (e), which employs a similar air –fuel lance (f), with additional lump coal charged separately as reductant.

Figure 13. Isasmelt lead process

a) SO_2 gas cooling and cleaning; b) Oxidation; c) Lance for oil and air; d) Feed mixing; e) Reduction furnace; f) Lance for oil and air; g) Reduction gas cooling and cleaning

Starting in 1983, a 5 t/h concentrate feed demonstration plant was used to prove the smelting stage of the process. In the first year of operation, 21 000 t of lead concentrate were treated to produce high-lead monoxide slag, which was subsequently processed by sintering and blast furnace reduction. In 1985, construction of the second-stage reduction vessel demonstration plant was started. At the present time the installation of a full-scale production plant at Mount Isa is being studied.

A cross-section of the oxidation furnace is shown in Figure 13 (b). The furnace consists of a cylindrical steel shell, 2.7 m in diameter and 4.5 m high, lined with chrome magnesite bricks backed with an insulation lining. Typical analyses are given in Table 3. Operating conditions for the demonstration plant are as follows:

Lead concentrate rate	4 t/h
Smelting temperature	1 030 °C
Air: concentrate ratio	125 % of theoretical
Fume rate	10 % of lead in feed
Flux addition	12 % of concentrate rate
Oil requirement	25 kg per tonne of concentrate

Table 3. Typical analyses from the Isasmelt demonstration plant oxidation vessel

Component	Lead concentrate, %	Slag product, %
Pb	47.3	51.8
Zn	7.0	7.6
Fe	12.4	13.6

SiO_2	2.8	9.8
CaO	0.9	1.5
S	23.8	0.3

4.4.4. *Oxygen – Slag Bath Smelting, QSL Process*

The QSL Process is named after its inventors, P. E. QUENEAU and R. SCHUHMANN Jr., as well as the process developers Lurgi Chemie [21]. Development of the process progressed through bench-scale tests in 1974 – 1975, pilot-plant operation in 1976 – 1979, and a demonstration plant operation at Metallhüttenwerke, Berzelius, Duisburg, Federal Republic of Germany from 1981 to 1985. At present three commercial plants are under construction in Trail, Canada (Cominco Ltd.), the Federal Republic of Germany (Berzelius Binsfeldhammer Smelter), and the Peoples Republic of China. Operation of the Canadian plant is scheduled for late 1989.

Figure 14 shows the general scheme of a QSL process lead smelter. Lead concentrate, fluxes, auxiliary coal fuel, recycle flue dust, and other charge components are blended (b) in a moist condition to form a single feed charge to the QSL reactor. The reaction vessel is a horizontal refractory-lined cylinder that is divided by a partition wall into an oxidation section (c) and a slag reduction section (d). The working dimensions of the demonstration plant reactor (10 t concentrate per hour, 30 000 t of lead per year) were 2.5 m (diameter) by 22 m (length, 7 m of which is occupied by the oxidation zone). Nitrogen-shrouded tuyeres on the bottom of the reactor injected oxygen into the oxidation section. Similar shrouded tuyeres were employed for submerged combustion of oxygen – coal or oxygen –natural gas reduction mixtures. Blended feed was charged through ports at the top of the oxidation reaction section into the injection-agitated lead and slag bath.

Figure 14. QSL lead smelting process

a) Oxidation gas cooling and cleaning; b) Feed mixing; c) Oxidation section; d) Slag reduction section; e) Reduction gas cooling and cleaning

The oxidation products in the QSL process are high-lead slag, sulfur dioxide gas, flue dust, and lead bullion. The amount of lead produced in the oxidation zone depends on the charge makeup and lead concentrate grade. Slag from the oxidation zone flows through an underflow port in the vessel partition wall into the slag reduction zone (d). Lead bullion is removed by a lead syphon at the side of the vessel. The smelting vessel is rotated by 90° during stoppages to bring the injection tuyere systems above the vessel slag level. Inspection of the refractory and tuyere maintenance can be carried out with the vessel in this standby position.

Figure 15 shows the QSL smelting plant in Trail, Canada. The reaction vessel has dimensions of 4.5 m (diameter) by 12.5 m (length) in the oxidation section, and 4.0 m (diameter) by 28 m (length) in the reduction section. Nominal plant capacity is 160 000 t/a of lead and 230 000 t/a of reduced slag. Reduction is performed with partially combusted natural gas.

Three smelting vessel configuration options are shown in Figure 16.

Figure 16. QSL smelting vessel configurations

A) Conventional, low arsenic – antimony bullion; B) Increased arsenic – antimony recovery in bullion; C) Recovery of zinc oxide fume

Figure 16 A. This is the simplest smelting configuration and is employed at the Duisburg demonstration plant. Reduction gas and oxidation gas flow into the same gas cooling system. Reduction and fuming of zinc in the reduction zone is controlled to limit zinc circulation in recycle flue dust. Lead bullion produced in the reduction zone flows countercurrent to oxidation slag through the partition wall underflow port. The product lead bullion is withdrawn from the oxidation end of the furnace. With this configuration the arsenic and antimony contents are minimized in the bullion and maximized in the reduced slag.

Figure 16 B. This differs from the previous option in that the product bullion syphon is located on the reduction side of the slag partition wall. Arsenic and antimony in bullion are maximized with this option.

Figure 16 C. This smelting vessel configuration has an auxiliary gas offtake at the reduction end of the vessel for withdrawing a zinc-bearing reduction fume. The lead syphon is located on the reduction side of the partition wall for

maximum arsenic and antimony deportment to bullion. This design is employed in the Cominco Trail smelter.

4.5. Other Lead Processes

Several other lead processes have been tested on small and pilot scales but none has been commercialized. The *Halkyn process* involves the fused-salt electrolysis of lead sulfide dissolved in molten lead chloride; it has been modified and improved, most by the U.S. Bureau of Mines [22]. Trouble-free fused-salt electrolysis is feasible only with high-quality lead concentrates; high contents of impurities (e.g., copper) cause the formation of barrier layers and cell complications.

Wet processes have not succeeded although many have been investigated in the chloride, nitrate, sulfate systems, and with selective alkylamine leaching of lead sulfate followed by carbonation of lead. An alternate leaching system employs ammoniacal ammonium sulfate, which also dissolves lead sulfate well and is cheaper than the amine solutions.

[Top of Page]

5. Refining of Lead Bullion

Charles A. Sutherland and Edward F. Milner

Production lead, known as bullion, contains numerous dissolved impurities. Molten lead is an excellent solvent for a variety of metals and compounds, and raw bullion commonly contains copper, iron, zinc, sulfur, arsenic, tin, antimony, bismuth, noble metals (silver, gold, platinum-group metals), oxygen, and occasionally nickel, cobalt, and tellurium. The lead content varies between about 90 and 99.9 % depending on the process and feed quality. The percentages of impurity contents for blast-furnace lead bullion treated in refining plants are as follows:

Cu	0.2 – 4.0
Fe	0 – 0.5
Zn	0 – 0.5
Ni	0 – 0.1
Co	0 – 0.1
As	0 – 2.0
Sb	0 – 6.0 (usually < 2.0)
Ag	0 – 2.0
Bi	0 – 6.0 (usually < 2.0)
Sn	0 – 4.0 (usually < 1.0)
S	typically 0.2 – 0.3
O	typically 0.1

The object of lead bullion refining is to produce pure commercial lead metal and to separate the valuable impurity metals into their most valuable marketable form. The two main refining routes used are pyrometallurgical and electrolytic. The latter is generally reserved for higher levels of impurities (especially bismuth).

Pyrometallurgical processes are generally operated in a batch manner; however, continuous operation is being applied to many of the process steps. The advantage of pyrometallurgical refining lies in the consecutive selective recovery of impurity metals.

In *electrolytic refining,* all the impurities are concentrated in the anode slime and must be separated by a relatively complicated process. On the other hand, electrolysis yields lead that is very low in bismuth (< 10 g of bismuth per tonne of lead), which cannot be economically produced by the pyrometallurgical route. Over 90 % of installed capacity for lead-bullion refining worldwide is based on pyrometallurgical methods.

5.1. Pyrometallurgical Refining

Principles. When metals are refined pyrometallurgically, impurities dissolved in the parent metal are enriched in a phase that is insoluble (or sparingly insoluble) in the parent metal. Enrichment can be achieved by adding reagents, by controlling the pressure and temperature, or by a combination of both techniques. Methods are classified as chemical, precipitation, and distillation processes.

Attention to the kinetics of the unit operations involved in lead refining is of the utmost importance. Kinetic factors can govern the degree of refining that is attainable when the system is far removed from the theoretical chemical or physical equilibrium. In other systems the chemical equilibrium is approached closely. A good review of the physical chemistry is given in [23].

Chemical Processes. A reagent added to the parent metal reacts with one or more impurities to form a compound that is insoluble in the parent metal. Occasionally, fluxes are also used, for example to cause oxides formed in the solid phase to go into a liquid slag. Reagents include oxygen (atmospheric oxygen or oxygen-evolving salts), sulfur, and chlorine. The refining step is then referred to as selective oxidation, sulfurization, or chlorination. Reagent selection is based on a comparison of the free energy of formation of the oxides, sulfides, or chlorides of the parent metal and of the impurities in question.

Precipitation Processes. Generally, impurities become less soluble in the host metal as the temperature falls, and can be rejected either directly from the melt (e.g., copper from the binary system copper – lead), or as a compound with the parent

metal (e.g., iron as $FeZn_3$ from iron – zinc solutions). Alternatively, suitable reagents can form insoluble compounds that can be skimmed off (e.g., bismuth from lead – bismuth solutions after addition of calcium and magnesium); this is really a chemical process that involves the formation of insoluble intermetallic compounds.

Distillation Processes. Distillation processes are employed when a large difference in vapor pressure exists between the parent metal and the impurity (e.g., in the separation of residual zinc from lead bullion after Parkes desilvering).

Process Steps. All of the above processes are used in the pyrometallurgical refining of lead bullion. A typical pyrorefining scheme is as follows:

1. *Removal of copper* is a two-stage operation. The first stage is primary decoppering by *drossing* (precipitation). The second is *selective sulfidizing* of copper by the Colcord process, which involves the addition of sulfur (a chemical process).
2. *Removal of arsenic, tin, and antimony* by selective oxidation with injected air or with oxidizing agents such as sodium nitrate in a caustic slag (Harris process).
3. *Removal of noble metals* is usually called desilvering or desilverizing and involves intermetallic precipitation with zinc by the Parkes process.
4. *Removal of zinc* remaining after desilvering is achieved by vacuum distillation.
5. *Debismuthizing.* If required to meet refined lead specifications, bismuth is removed by precipitation with alkali metals and/or alkaline-earth metals, for example with calcium and magnesium in the Kroll – Betterton process.
6. *Removal of alkali metals and alkaline-earth metals* remaining after debismuthizing is called final refining and is performed by selective oxidation with air under a salt slag cover.

5.1.1. *Decoppering*

Drossing (Liquation). Copper is soluble to several percent in hot lead bullion but to only 0.06 % at the freezing point. When the lead cools, copper and other impurities precipitate as a lead-rich *copper dross*. This process is always the first step in any lead refining operation. In the first phase of cooling to about 950 °C, nearly all dissolved iron and zinc are precipitated as oxides, magnetites, or spinels. The noble metals and other impurities with higher solubilities (e.g., copper, arsenic, antimony, tin, bismuth) remain dissolved in the lead.

In the next cooling stage, the copper compounds of sulfur, arsenic, antimony, and tin separate, along with considerable lead sulfide and entrained metallic lead. The large lead content must be separated by a dross retreatment process. Nickel and cobalt, if present, separate similarly to copper.

Fine decoppering may also be referred to as sulfur decoppering or sulfur drossing (Colcord process). After drossing, elemental sulfur is mixed into the molten lead bullion at the lowest possible temperature (320 °C) for selective sulfidization of copper. Lead(II) sulfide and copper (II) sulfide form stable phases in the ternary system Pb – Cu – S when liquid or gaseous sulfur is present. The copper sulfide can be produced by the reaction between copper – lead alloy and liquid or gaseous sulfur whenever there is a local excess of sulfur:

$$(\mathrm{Cu})_{\mathrm{Pb}} + \mathrm{S} \rightarrow \mathrm{CuS}$$

Copper(II) sulfide can decopper lead by the reaction

$$(\mathrm{Cu})_{\mathrm{Pb}} + \mathrm{CuS} \rightarrow \mathrm{Cu_2S}$$

Sulfur simultaneously reacts with lead, but much more slowly than with copper:

$$\mathrm{Pb} + \mathrm{S} \rightarrow \mathrm{PbS}$$

The lead corner of the Pb – Cu – S system is shown in Figure 17 and suggests that the copper level can in theory only be decreased to about 0.05 % by sulfur precipitation. With cooling, however, lead sulfide forms as well as copper (I) sulfide (Cu_2S). In fact copper levels of 0.001 – 0.002 % can be achieved if minor amounts of silver or tin are also present and attention is paid to good shear stirring and gradual addition of sulfur [23]. This is because silver and tin slow down the reaction between lead and sulfur. Without silver or tin, 0.01 % copper can be attained only by repeated sulfur additions and with prohibitive sulfiding of lead.

Figure 17. Lead corner of the Pb – Cu – S ternary system [23]

Process Engineering. Decoppering of lead bullion usually takes place immediately after the bullion is discharged from the blast furnace. In *batch decoppering,* drossing is carried out in kettles with capacities of up to 300 t. Powerful stirrers help separate the phases, allowing the formation of a " dry " dross containing little entrained lead metal. The dry dross is removed from the melt surface by skimming, usually with mechanically or pneumatically driven perforated scoops, or by suction. In industrial drossing, final copper contents of 0.06 – 0.12 % are reached. This level of copper would greatly increase the zinc requirement for Parkes process desilvering, and therefore fine (sulfur) decoppering is always necessary.

An important advance is *continuous decoppering*, which combines decoppering and reprocessing of the copper dross in a

single stage. Continuous drossing has several advantages over the batch process of dry stirring in kettles. Effective lead drossing by cooling is combined with the formation of matte and slag in a single process step. Handling of dusty copper dross is eliminated, which permits a major improvement in plant hygiene. Success in the development of a continuous drossing process has been achieved in Australia and the former Soviet Union by using a deep lead bath reverberatory furnace. The process is also employed at Cominco's lead smelter in Trail, Canada.

Figure 18 shows the furnace used by Broken Hill Associated Smelters (BHAS) in Port Pirie, Australia. The gas-fired furnace has an external bullion cooling launder (h) with immersible water-cooled plates (j). Hot bullion from the blast furnace is charged to the drossing furnace and is cooled by mixing with colder lead from the cooling launder. Dross formed rises to the heated surface and is melted to matte and slag. The third-generation furnace now used at Port Pirie has hearth dimensions of 6.15 m by 2.0 m and a depth of 1.7 m [24]. The process is best suited to refining lead with a fairly uniform impurity content. An important operating criterion is the ratio of copper to sulfur in the bullion. A high ratio causes the formation of high melting point speiss crusts in the furnace. Recent development has allowed addition of elemental sulfur to the furnace permitting satisfactory operation at bullion copper levels approaching three percent.

Figure 18. Plan view of the continuous drossing furnace of Broken Hill Associated Smelters at Port Pirie, Australia

a) Product drossed lead; b) Slag and matte tapping spout; c) Circulating pump pot; d) Gas burners; e) Charge port; f) Ventilation; g) Return launder pot; h) Cooling launder; i) Water-cooled flue; j) Water-cooled plates

In the Russian continuous drossing process, bullion cooling is achieved by indirect water-cooling through the furnace bottom. Copper drossing and cooling are finished in batch kettles, dross being recycled to the drossing furnace. Soda ash is added to the furnace to produce a low lead soda matte.

Sulfur Drossing. *Final decoppering* (sulfur drossing) is carried out *batchwise* in most plants in kettles fitted with a powerful stirrer. Fine sulfur is added in increments to the lead vortex at 330 – 340 °C, and the formed copper dross is skimmed, usually with the aid of sawdust. This dross is much lower in copper (and higher in sulfur) than primary decoppering dross and is returned to a convenient point in the smelting process. In industrial operation, about 1 kg of sulfur is added per kilogram of copper; the end copper content must be less than 50 g/t if possible. Several sulfur treatments are needed to achieve this.

A *continuous sulfur drossing system* has been developed by BHAS at Port Pirie [24] and has been operating since 1981. The process employs a series of small stirred kettles [23]. A continuous flow of bullion from the copper drossing furnace is cooled, treated with elemental sulfur, and mechanically drossed.

5.1.2. *Removal of Arsenic, Tin, and Antimony*

The removal of arsenic, tin, and antimony is called *softening* . Two processes are in use: selective oxidation with air in fired furnaces and the Harris process.

Oxidation in Air-Blown Furnaces. This method is based on the fact that tin, arsenic, and antimony react more readily with oxygen than lead, and are oxidized (in the order listed) before lead at 700 – 750 °C. Air is injected through vertical lances onto the surface of a lead bath in a rectangular oil- or gas-fired reverberatory furnace. The oxides of tin, arsenic, antimony, and lead form a fluid slag, which is periodically removed from the surface of the lead bath. A considerable amount of lead is oxidized and the slag generally contains 50 – 60 % lead monoxide. In batch reverberatory softening, segregation of slag skimmings into high arsenic – tin and high antimony lots is possible, but not usually practised.

The oxides float on the molten lead and are withdrawn as softening slag. Refining time depends on the amount of impurities in the charged bullion and also on the air-lancing method. Impurity oxidation rates in the order of 4 kg m^{-2} h^{-1} are typical.

Continuous bullion softening is operated by BHAS, Port Pirie, Australia. Drossed lead is pumped continuously into a softening reverberatory furnace fitted with an air-lance system similar to a batch softening furnace. The rate of bullion feed and the rate of arsenic and antimony oxidation are such that the antimony content is maintained at 0.02 – 0.05 %. Antimony oxidation rates of 40 kg m^{-2} h^{-1} are achieved, about an order of magnitude greater than in batch softening.

Harris Process. The Harris process employs molten sodium hydroxide as a medium for the oxidation of arsenic, tin, and antimony from lead bullion. Metallurgie Hoboken – Overpelt (MHO) Hoboken, Belgium [25] and the Norddeutsche Affinerie, Hamburg, Federal Republic of Germany [26], use this process. Harris refining is performed batchwise using a reaction cylinder holding molten sodium hydroxide installed in a lead kettle. Figure 19 shows one half of a dual kettle Harris reactor as employed by MHO at the Hoboken smelter. Bullion is pumped through the Harris reactor caustic charge until the required degree of impurity removal is achieved. A valve at the bottom of the caustic vessel is then closed allowing the loaded caustic to be discharged to a transport ladle for subsequent hydrometallurgical processing. Fresh molten caustic recovered from the salt processing plant is charged to the reactor by ladle for the next refining cycle.

Figure 19. Harris reactor at Metallurgie Hoboken – Overpelt S.A. [25]

One half of the dual reactor is shown.a) Lead bullion; b) Lead bullion pump; c) Molten caustic holding vessel; d) Molten caustic supply ladle; e) Reactor control system

The Harris process is the preferred softening process for lead bullion containing high levels of impurities. The MHO plant at Hoboken can remove up to 400 t of arsenic, tin, and antimony from lead bullion per month.

Harris softening involves the oxidation of arsenic, tin, and antimony by air or by sodium nitrate added to the caustic bath. The oxidation products, in order of their formation, are sodium arsenate, sodium stannate, and sodium antimonate:

$$2\,As + 2\,NaNO_3 + 4\,NaOH \rightarrow 2\,Na_3AsO_4 + N_2 + 2\,H_2O$$

$$2\,Sb + 2\,NaNO_3 + 4\,NaOH \rightarrow 2\,Na_3SbO_4 + N_2 + 2\,H_2O$$

$$5\,Sn + 4\,NaNO_3 + 6\,NaOH \rightarrow 5\,Na_2SnO_3 + 2\,N_2 + 3\,H_2O$$

Tellurium is oxidized to sodium tellurate and telluride:

$$3\,Te + 6\,NaOH \rightarrow 2\,Na_2Te + Na_2TeO_3 + 3\,H_2O$$

$$xTe + Na_2Te \rightarrow Na_2Te_{x+1}$$

The arsenic salt is soluble in the molten caustic whereas the salts of tin and antimony form a solid suspension. Because of the reversibility of the oxidation chemistry (e.g., Na_3SbO_3 will oxidize arsenic and tin from bullion), a loaded caustic salt is produced that is high in arsenic and tin, followed by a salt containing primarily antimony. Table 4 gives the distribution of arsenic, tin, and antimony in the products of the Harris refining process at the Hoboken lead smelter. A flow sheet is given in Section Processing of Intermediate Products of Pyrometallurgical Refining (Fig. 24).

Table 4. Distribution of metals in products separated by the Harris process at Metallurgie Hoboken – Overpelt S.A. [23]

Product	Metal, wt %		
	As	Sn	Sb
Lead particles As-Sn	5.5	5.0	2.1
Lead particles Sb	0.2	0.1	4.0
Black antimonate **	0.5	2.5	3.8
Calcium stannate	2.2	91.8	0.2
Calcium arsenate	91.6	0.5	0.3
White antimonate		0.1	89.6

* For origin of products see Figure 24, p. 222.
** Contains more than 80 % of extracted Te, Se, and In.

5.1.3. *Removal of Noble Metals*

Noble metals and residual copper are removed from lead by the Parkes process in which zinc metal is added to the molten silver-bearing lead and the mixture is cooled (see also ⟶ Silver, Silver Compounds, and Silver Alloys). Silver – zinc mixed crystals precipitate out and rise to the bath surface as a crust (Parkes process crust). The intermetallic compounds have a higher melting point than lead and are virtually insoluble in zinc-saturated lead.

The metallurgical operations in the Parkes process are based on the lead corner of the ternary system Ag – Pb – Zn (Fig. 20). Most of the silver removal takes place in the liquid + ϵ-phase Ag – Zn crystals region; the last crop of crystals in the latter part of the second stage comes from the liquid + η-phase region. Silver removal is very efficient and depends on the quantity of zinc and the number of stages used, but it is usually not economical to use more than two stages.

Figure 20. Lead corner of the Pb – Ag – Zn system in rectangular coordinates [23]

The isotherms (—– – —– –) indicate how much zinc can be dissolved in the lead. The cooling curves (— — —) indicate the course of desilvering in the batchwise two-stage process for final silver concentrations of 5 and 10 ppm.

Process Engineering of Desilvering. In the *batch process,* desilvering is performed in two stages in kettles with capacities of up to 300 t. In the first stage " lean crust " from the preceding charge is added along with other recycle zinc (see Section Dezincing) and stirred into new softened lead at 460 °C. The " rich crust " is skimmed off for silver recovery. In the second stage, zinc metal is added with stirring; more zinc – silver crystals form, and the bath is then cooled to near freezing at about 370 °C so that the last crystals separate. At this point, the silver content of the near-freezing lead is 5 – 10 ppm.

The *Williams continuous desilverizing process,* developed at Port Pirie, employs a deep kettle surrounded by heating jackets, which impose a vertical temperature gradient on the lead column from 600 °C at the top to the temperature of the ternary Ag – Pb – Zn eutectic at the bottom. The upper part of the column contains ports for the intake of lead, addition of zinc, and removal of the ternary alloy. A siphon for discharging the desilvered lead has its intake just above the bottom of the kettle.

The softened silver-bearing lead is brought to 650 °C in a conditioning furnace and then flows continuously into the desilvering kettle. The lead flows through the zinc layer in the upper part of the kettle, and becomes saturated with zinc. As it descends down the kettle, it is cooled along the imposed temperature gradient. When it approaches the freezing temperature, silver – zinc crystals precipitate and rise to the zinc layer at the lead surface. The desilvered lead contains about 3 ppm Ag and 0.6 % Zn, and leaves the kettle through the siphon.

The composition of a fresh zinc layer changes, becoming enriched in silver (and lead). When it approaches about 15 % silver, 20 % lead, it begins to freeze. The mushy alloy is then ladled out and replaced with fresh zinc. Residual copper and any gold are removed very efficiently along with the silver. Continuous desilvering produces only a single silver-zinc crust which can be sent directly to distillation—an advantage over two-stage desilvering. The modern batch operation, however, uses less zinc and has lower operating costs.

5.1.4. *Dezincing*

The desilvered lead still contains about 0.55 –0.6 % zinc which must be removed. Older methods used air and steam, caustic soda, or chlorine, all of which oxidized the zinc metal. These have been replaced by vacuum distillation of zinc from the desilvered lead.

The large difference in vapor pressure between the host lead and dissolved zinc permits the volatilization of about 95 % of the zinc from the desilvered lead when a vacuum of about 0.133 Pa is applied at about 600 °C. A condensing surface placed close to the surface of the lead allows kinetic control of the distillation. The zinc content of the vapor exceeds the mole fraction in the melt by over 500 % [23].

Process Engineering. *Batch dezincing* is performed in a kettle: a water-cooled bell is sealed vacuum-tight on the kettle and distillation is carried out at about 600 °C and a vacuum of about 0.133 Pa (measured at the pump). The lead is circulated by a stirring mechanism, also sealed vacuum-tight. Crystalline zinc precipitates on the bottom of the water-cooled vacuum bell and is struck off after the termination of the process. Adequate sealing was originally achieved by letting the bell dip into the lead bath (barometric seal); water-cooled gaskets are preferred.

At Port Pirie, *continuous dezincing* has also been developed. The dezincing apparatus (Fig. 21) consists of a thin-film evaporator with roughly 0.75 m^2 of evaporating surface. It can dezinc 16 – 37 t/h of Parkes lead, and 90 – 95 % of the zinc content is recovered on a water-cooled fin condenser. When about 3 t of zinc has been collected, the condenser is replaced. The deposited zinc is melted and returned to the desilvering operation (see Section Removal of Noble Metals).

Figure 21. Continuous vacuum dezincing

a) Water-cooled cover; b) Hook; c) Window; d) Cooling water connections; e) Rubber gasket; f) Baffle; g) Cooling fins; h) Weir plate; i) Lead trough; j) Level control; k, l) Furnace setting gas entry and exit; m) Lead inlet to trough; n) Evaporation surface; o) Reinforcement; p) Flexible connection; q) False bottom; r) Lead outflow; s) Lead siphon; t) Vacuum connection; u) Drain

The lead is heated to 590 – 620 °C in a preheat furnace, before entering the vacuum kettle. After dezincing, it leaves the unit at 540 – 560 °C with a zinc content of about 0.03 %. The pressure inside the kettle is 3 – 7 Pa. The residual zinc in the lead bullion is removed during final refining (Section Final Refining and Casting of Lead).

5.1.5. *Debismuthizing*

Debismuthizing is the last step of lead-bullion refining (see also ⟶ Bismuth, Bismuth Alloys, and Bismuth Compounds – Crude Bismuth from Lead Concentrates). It is applied when the bismuth content of the ore is so high that it restricts the use of the soft lead smelted from it. When possible, bismuth-rich and bismuth-poor ores are smelted separately in order to refine

the minimum amount of lead bullion with the maximum bismuth content.

Bismuth is less reactive than lead, therefore it cannot be removed with oxygen, chlorine, or sulfur. It is customarily separated by addition of an alkali metal or alkaline-earth metal forming a bismuthide M_xBi, but this only permits a minimum bismuth content of 0.03 %, which is not adequate for many requirements. The removal of bismuth to <0.01 % can be achieved by the *Kroll – Betterton process* , which uses calcium and magnesium and also by the *Jollivet – Penarroya process*, which uses potassium and magnesium. Only the former remains in use; the metallurgical reactions take place in the lead corner of the corresponding quaternary system (Fig. 22). Bismuth separates as a crust of the double bismuthide, $CaMg_2Bi_2$.

Figure 22. Lead corner liquidus of the quaternary Pb – Bi – Ca – Mg system [23]

The lowest attainable bismuth content is around 0.002 % at the quaternary eutectic point. Further addition of calcium and magnesium does not improve bismuth removal. The reagent requirement is given by the total calcium and magnesium needed for precipitation as the double bismuthide and for saturation of the lead.

Process Engineering. The Kroll – Betterton *batch debismuthizing process* is carried out in kettles. Magnesium and calcium (in lead) are stirred into the lead bath at a temperature of about 420 °C. The bath is then cooled to near the solidification point with slow stirring. The crust (enriched about 10 : 1 in bismuth) is removed in a similar manner to the Parkes process (see Section Removal of Noble Metals). The crust grade can be improved considerably by stirring into the next batch of lead. Both batch and continuous versions of the Kroll – Betterton refining are practiced. A procedure is also used for secondary, fine debismuthizing by antimony addition [27].

5.1.6. *Final Refining and Casting of Lead*

Refined lead contains arsenic, antimony, and tin at a level of 10 – 20 g/t; zinc corresponding to the final content in vacuum dezincing (ca. 30 g/t); and (if debismuthizing has been performed) calcium and magnesium corresponding to the saturation limit. These impurities are removed down to below 1 g/t by treatment with caustic soda and, in some instances, with sodium nitrate.

Most casting is done automatically in strip or (less often) bench form, in machines provided with automatic stacking devices. The casting temperature is around 400 °C. Immediately after admission to the chill mold, the thin oxide surface film is skimmed off. The cast lead has a coarsely crystalline surface; if final refining and casting techniques are correct, there are no temper colors.

5.1.7. *Processing of Intermediate Products of Pyrometallurgical Refining*

Copper Dross. Copper dross is a complex mixture of compounds (see Section Decoppering) and contains a substantial amount of sulfidic and metallic lead. Melting the dross in a retreatment furnace frees the metallic lead and forms a matte phase, consisting mainly of lead and copper sulfides, and a slag which contains metal oxides and often requires silicate fluxing. If arsenic is available and sulfur is deficient, a copper arsenide speiss product is formed. The slag is returned to the smelter, but the matte is a product for sale or further processing.

All constituents of the dross deport to the four possible liquated phases—lead, speiss, matte, and slag. If large amounts of arsenic are present, a speiss forms in which nickel, arsenic, and part of the copper are preferentially concentrated. If copper and arsenic levels in the dross are low, the matte and speiss must be enriched by a further treatment.

In dross retreatment, it is desirable to minimize the lead content of the final matte. If the iron and sulfur contents are known, the final lead content can be approximately estimated from Figure 23: % Fe is equated to % (Fe + Zn) in the lead-free matte and % S can be determined from the lead-free sum, Fe + Zn + Cu + S = 100 %. For example, for a lead-free matte containing 7 % Fe, 1 % Zn, 24 % S, and 68 % Cu, the lead content predicted from Figure 23 is 20 %. The final matte would then contain 20 % Pb, 5.6 % Fe, 0.8 % Zn, 19.2 % S, and 54.4 % Cu. This is a fair estimate only for low alkali mattes. Sodium or calcium additions lower lead solubility in the matte substantially; at 5 % sodium or calcium the solubility is reduced to less than 20 % of that in the same matte without alkali. This is the basis of the soda matte process used by Asarco (El Paso) and St. Joe Lead at Herculaneum, in which about 5 % soda ash is added to the dross during melting and produces a copper enriched matte.

Figure 23. Solubility of lead in Cu – Fe – S mattes [23]

The recovered lead contains most of the noble metals. Matte, and particularly speiss if present, also hold significant amounts of precious metals. Fume from the furnace is enriched in indium, tin, arsenic, and zinc. Slag, matte and speiss are normally

granulated.

Hydrometallurgical methods for treating copper dross involve solubilizing the copper for electrowinning either by pressure oxidation leaching in sulfuric acid or by ammoniacal leaching and solvent extraction.

Softening Slags and Drosses. Softening slag and skimmings with variable contents of tin, arsenic, and antimony (Section Removal of Arsenic, Tin, and Antimony) are usually reduced to hard lead. An effort is made to slag off part of the arsenic during reduction. The process is normally carried out in a rotary furnace, but can also be done in a blast furnace.

In the short rotary furnace at Port Pirie, 7 t of softening slag are reduced batchwise with the addition of 5 % soda, 7 % charcoal, and 6 % " caustic slag " from subsequent refining. The charcoal is added in two portions. After the first portion is reacted, a lead bullion containing 2 – 3 % antimony is tapped off and recycled. After the second reduction, about 85 % of the feed antimony is tapped off as an alloy containing 25 – 30 % antimony.

Harris Salt Slags. Harris slags (Section Removal of Arsenic, Tin, and Antimony) are processed to recover a large portion of the valuable minor metals as black antimonate (Sn, Sb, Te, Se, In) and sodium antimonate (Sb); to precipitate the tin as calcium stannate and arsenic as calcium arsenate; and to recover caustic soda for reuse. The flowsheet of Metallurgie Hoboken – Overpelt is shown in Figure 24.

Figure 24. Treatment of Harris salt slags at Metallurgie Hoboken-Overpelt S.A. [25]

Silver – Zinc Rich Crusts for Desilverizing. The purpose of processing the silver – zinc-rich crusts (see Section Removal of Noble Metals) is to recover a malleable rich lead that contains all the noble metals. Some of the lead and as much as possible of the zinc must be removed; the latter is reused. Removal is achieved by expression and/or liquation with production of a dry or liquated crust, followed by zinc distillation.

Expression is commonly carried out in an air-driven Howard press submerged in a liquid lead bath, and the lead content of the compressed crust is brought to 50 – 60 %.

Liquation. Alternatively the crust may be melted at about 600 °C under a salt cover and separated into a lead-rich lower layer, which is returned to desilverizing, and a zinc-rich upper layer which passes to zinc removal.

Distillation allows the zinc content of the liquated rich crusts to be recovered in metallic form so that it can be reused for desilvering lead bullion (see Section Removal of Noble Metals). Distillation can be performed either at STP in the Faber du Faur furnace or under vacuum in the Leferrer furnace.

In the older *Faber du Faur furnace,* liquated zinc-rich crust is placed in inclined bottle-shaped graphite retorts and heated to 1000 – 1500 °C. Zinc condenses in a separate receiver in liquid form and is tapped off periodically. A certain amount of dross (zinc dust) is also formed; since this contains noble metals, it is recycled to the process.

A more modern method is the *Penarroya – Leferrer vacuum distillation* with radiation heating. This runs at a temperature (600 °C) well below the melting point of silver and considerable lead must be added to the crust to hold the silver in solution when most of the zinc has gone. The zinc condenses as a liquid. Low frequency induction furnaces are also used.

The distillation residue consists of silver containing other precious metals, zinc, lead, and copper. Zinc, lead, and copper are removed by cupellation (air oxidation), and the silver bullion is separated from gold by electrolysis (⟶ Silver, Silver Compounds, and Silver Alloys). The cathode silver can be further refined by chlorination.

Bismuth Drosses. Bismuth dross (see Section Dezincing) can be processed by either pyrometallurgical or electrolytic methods. In either case, the reagents calcium and magnesium are first removed, so that the subsequent operations are always performed on a pure lead – bismuth alloy.

Lead is removed by selective chlorination of the lead – bismuth alloy with chlorine gas, lead being converted to lead chloride with virtually no loss of bismuth. The rate of lead chlorination in lead – bismuth alloys with > 85 % bismuth is extremely high at 700 – 800 °C. In practice, chlorine is injected into an alloy already enriched to this level, and lean material is simultaneously added. Operation is thus continuous and material throughput is constant. The crude bismuth usually has a low foreign element content (copper, noble metals), which is removed by a process similar to that used for the refining of lead bullion.

In comparison with the pyrometallurgical technique, the electrolytic method has the advantage that the lead is deposited in pure form at the cathode (generally as fine lead). The anode slime from electrolytic lead – bismuth separation is subjected to reduction melting; the product is an alloy containing > 90 % bismuth along with lead, copper, and noble metals. This alloy can be processed pyrometallurgically (selective chlorination) or by bismuth electrolysis.

5.2. Electrolytic Refining of Lead Bullion

The electrolytic refining of lead bullion from soluble anodes has been practised for years in a number of large plants. Because the poor solubility of lead sulfate rules out sulfate electrolysis, the only candidate electrolytes are the few readily

soluble lead salts. In practice, solutions used have been restricted to the lead salts of fluosilicic acid (H_2SiF_6), fluoboric acid (HBF_4) and amidosulfuric (sulfamic) acid (H_2NSO_3H). The most important of these is the fluosilicate electrolyte.

Metals with a higher electrochemical potential than lead (silver, gold, copper, bismuth, antimony, arsenic, and germanium) remain essentially undissolved and accumulate in the anode slime, which is processed to recover them. Metals with a lower potential, such as iron, nickel, and zinc do go into solution, but the feed lead bullion contains such low levels of them that enrichment in the electrolyte is insignificant. The deposition potential of tin, – 0.140 V, is close to that of lead, – 0.126 V. Tin is therefore deposited along with lead from both fluosilicate and fluoborate electrolytes. The amidosulfate electrolyte, on the other hand, allows separation of lead and tin because of the low solubility of tin sulfamate.

The undissolved impurities, if they are present in large enough quantities, form a porous skeletal coating (slime). The slime adheres to the anode and retains its initial form, so that cells need not be regularly cleaned and deslimed. The mechanical strength of the slime depends on the content of foreign metals in the anode. Higher contents of bismuth and antimony enhance strength; increasing copper leads to a dense slime, so that the feed must be decoppered to <400 g/t copper. The production of adherent anode slimes requires a minimum antimony and bismuth content of 1 – 1.2 %. The cell voltage rises with increasing thickness of the slime coating and may reach up to twice the initial voltage; thus, energy consumption imposes an economic limitation. In addition, the increasing voltage can lead to dissolution of antimony, arsenic, and bismuth from the slime. The residence time of the anodes in the cell, is governed by this rise in cell voltage and thus by the concentration of impurities in the anode lead.

In industrial electrolytical lead refining, the *Betts process,* an aqueous solution of fluosilicic acid and lead fluosilicate ($PbSiF_6$) is electrolyzed. One liter of electrolyte contains 60 – 100 g lead as fluosilicate and 70 – 120 g free H_2SiF_6. Glue and/or other organic inhibitors (300 – 500 g per tonne of electrolytic lead) are added to obtain smooth deposits. Electrolyte losses result from the decomposition of H_2SiF_6 and entrainment in the anode slime.

The consumption of H_2SiF_6 is around 2 kg per tonne of electrolytic lead. The lead content of the electrolyte rises slowly because of the difference in current efficiency between anode and cathode. This increase is sometimes offset by precipitation of lead sulfate after addition of sulfuric acid. However, the lead content is usually held at the desired level by electrolysis in separate cells with insoluble graphite anodes. The following reactions take place:

Anode	$H_2O \longrightarrow 2\,H^+ + 1/2\,O_2 + 2\,e^-$
Cathode	$PbSiF_6 + 2\,H^+ + 2\,e^- \longrightarrow H_2SiF_6 + Pb$
Total	$PbSiF_6 + H_2O \longrightarrow H_2SiF_6 + Pb + 1/2\,O_2$

Cathode blanks are made of electrolytic lead and are 0.8 – 1 mm thick. They are fabricated either by casting over an inclined plane (older procedure) or with a water-cooled drum that dips into the lead bath. One or two cathode changes are generally required per anode. Current densities are 150 – 240 A/m^2 at the anode and 130 –220 A/m^2 at the cathode. Current efficiency is 85 – 95 % and energy consumption about 190 kWh per tonne of electrolyte lead. After electrolysis has been completed the anodes have about 30 – 40 % of their starting weight and are melted down into new anodes. The cathodes are thoroughly cleaned, melted down, refined with soda in a kettle to eliminate residual antimony, arsenic, and tin, and cast into ingots.

The size and weight of the electrodes used for lead electrolysis at the Cominco lead refinery in Trail, Canada are given in Table 5. Other important data follow [28]:

Lead electrofining data, Cominco Trail plant

Processing of Anode Slime. The composition of the anode slime depends directly on the impurities in the anode lead. In general, anode slime contains not only noble metals but also high levels of bismuth and antimony. Different compositions are seen at plants that have modified their operation for bismuth recovery. For example, at the Norddeutsche Affinerie, the anode lead consists of bismuth drosses and high-bismuth lead that has gone through the entire thermal refining process except for Kroll – Betterton debismuthizing.

No single processing method has been devised for such diverse intermediate products. By way of example, Figure 25presents the flowsheet of the Cominco refinery in Trail. The combination of proven pyrometallurgical processes yields product lead, dore (gold – silver), antimonial (hard) lead, and bismuth metal. The complexity of anode-slime processing places some restrictions on the inherently elegant electrolytic refining technique.

6. Recovery of Secondary Lead from Scrap Materials

Charles A. Sutherland and Edward F. Milner

The total world production of refined lead in 1987 was estimated to be 5.6×10^6 t. Of this approximately 60 % was primary lead from lead ores and concentrates; the remainder (40 %) was secondary lead produced from scrap materials. As the consumption of lead for sheet, pipe, and cable sheathing has declined and consumption for lead – acid storage batteries has increased, the secondary lead industry is primarily concerned with the processing of scrap batteries. In recent years the industry in the United States, and to a lesser extent in Europe, has experienced new, more stringent environmental regulations, and very low lead prices in the mid-1980 s. These factors have brought about the closure of a large number of small-scale secondary processing operations, and provided the impetus for the development of improved technology. Besides improving plant working conditions and reducing ambient lead emissions, an important objective of new environmental regulations is to force the efficient recycling of lead – acid batteries and prevent disposal in municipal waste sites. The potential generation of acetic acid and contamination of ground water with soluble lead acetate is the basis for this regulatory pressure. In the Federal Republic of Germany the efficiency of spent battery recycling is claimed to be 90 %.

6.1. Battery Types and Composition

Lead – acid storage batteries (⟶ Batteries – Battery Properties and Characteristics) are of three general types:

1. SLI (Starting, Lighting, Ignition) batteries, the bulk of which are automotive;
2. traction vehicle batteries; and
3. stationary batteries for supplying emergency power.

The key components in all these types are:

- a polypropylene containment box
- grids, connectors, and poles of lead alloy
- electrode paste: mixture of lead sulfate and lead oxides
- grid separators of poly(vinyl chloride) (PVC)
- sulfuric acid

The approximate composition of these materials on a weight percentage basis is:

Lead alloy components	21
Lead oxide	16
Lead sulfate	24.5
Water and sulfuric acid	24
Polypropylene	7.7
Poly(vinyl chloride)	3.8
Others	3.0

6.2. Battery Breaking and Processing Feed Preparation

Scrap battery preparation has progressed through four levels:

1. Acid drainage followed by pyrometallurgical processing of the entire battery and case. This blast furnace smelting approach became increasingly difficult with the change from bakelite to easily-fused polypropylene battery cases [27].
2. Separation of acid and case, both of which went to waste as gypsum (after neutralization with lime) and plastic garbage, respectively. The remaining mixture of poles, grids, grid paste, and PVC separators became secondary smelter feed.
3. Mechanical shredding of batteries followed by heavy medium separation to produce
   - Drainage acid for sale or limerock neutralization to produce gypsum as waste
   - Clean polypropylene for sale and recycle
   - A clean metallic fraction which can be smelted at low temperature
   - Battery paste mixture of $PbSO_4$ and PbO_x
   - Clean PVC plastic to waste or recycle
4. The same as (3) except that battery paste and drainage acid are reacted with sodium carbonate to produce dry crystals of sodium sulfate, a saleable product [28]. This system has several advantages. The sulfur content of the lead-bearing feed materials is largely eliminated, thus simplifying the subsequent smelting processes and reducing the amount of waste sulfur and lead-bearing slag. Figure 26 shows the flowsheet of the Tonolli CX process as an example.

Figure 26. CX scrap battery components recovery plant

6.3. Smelting of Battery Scrap Materials

The metallurgical equipment used for treating battery scrap consists of blast furnaces, reverberatory furnaces, rotary kilns, and short rotary furnaces.

Blast Furnace Treatment of Battery Scrap [29-32]. Typical blast furnace charge consists of cased batteries and battery plates with paste, limestone flux, scrap iron, metallurgical coke, and miscellaneous recycle drosses and slags.

Blast furnaces used for battery scrap smelting are smaller than primary lead industry blast furnaces. Typical hearth areas are in the range of 2 – 5 m^2. Smelting products are lead bullion containing most of the antimony content of the charge, iron matte containing most of the sulfur in the charge, slag, and flue dust which must be melted or agglomerated for recycle.

Plastic materials in the charge can, through fusion, impede the flow of material in the furnace shaft. This adverse effect is controlled by recirculating crushed slag in the furnace charge. Volatile organics in the off-gas must be combusted in an afterburner to prevent baghouse operating problems.

With advanced battery feed preparation systems (see Section Battery Breaking and Processing Feed Preparation), the role of the blast furnace in the industry is expected to decline in favor of reverberatory or rotary furnace reduction of lead carbonate – oxide sludge and metallic grid products.

Rotary Kiln Smelting of Secondary Lead. Continuous processing with long rotary kilns was developed by Preussag AG, Goslar, Federal Republic of Germany, and is practised in several other locations [33]. A typical equipment layout for this type of plant is shown in Figure 27. The kiln charge consists of a plastic-free mixture of sulfate, lead posts, grids, metallic iron, soda ash, coke breeze, and recycle flue dust. Products are lead bullion and a mixed matte – slag material for discard.

Figure 27. Rotary kiln scrap battery smelting plant

Short Rotary Furnace Smelting. The short rotary furnace is extensively used for smelting battery scrap materials [34]. Typical furnace dimensions are a diameter of 3.5 – 4.0 m and a length of 4 – 5 m. Reverse-flow firing is usually employed with the combustion burner and gas offtake at one end of the furnace. The charge components and general metallurgy are very similar to the rotary kiln process. The main difference is batch rather than continuous operation, which allows the use of different charges for the production of high- or low-antimony bullion products.

Reverberatory Furnace Smelting. The reverberatory furnace, although generally less productive than rotary furnaces, provides good control of the reduction potential required to produce low-antimony bullion and retain antimony in slag for subsequent reduction to high-antimony bullion. Reduction of desulfurized battery paste is also readily achieved at low temperature in reverberatory furnaces.

6.4. Future Trends

Increased environmental pressure is expected to continue to force innovation in secondary lead recovery. Slags produced by thermal reduction processes are classified as hazardous waste in the United States. Further electric furnace reduction of slag is now being practiced by the RSR Corporation in the United States to make slags acceptable for non hazardous disposal.

The lead – acid (SLI) battery industry is changing to sealed low-maintenance designs which require high-purity lead for the calcium – lead alloy grids. The secondary industry has been forced to produce an increasing percentage of high-purity lead compared to the grades of antimonial lead produced in the past. Removal of antimony by kettle – caustic softening is costly. The incentive to separate battery scrap into low-antimony paste and high-antimony metallic components for separate processing is thus expected to increase.

The search for nonthermal processes for high-purity lead recovery, particularly from desulfurized battery paste, is expected to intensify. Research work by the U.S. Bureau of Mines [35], and the RSR Corporation in the United States and Technologie Tonolli (Italy) on a fluosilicic acid leach – electrowin method of treating lead carbonate – oxide paste is expected to be used commercially in the early 1990 s.

[Top of Page]

7. Uses of Lead

Charles A. Sutherland and Edward F. Milner

The trend in end-use consumption of lead over the period 1977 – 1987 is illustrated in Table 6 for the United States, Japan, and Western Europe. A more thorough breakdown compiled by the Lead Development Association and the Lead – Zinc Study Group for presentation to the " Metals 2000 " Conference is drawn upon for the following analysis.

Table 6. Consumption of lead by end-use (%)

Use	United States		Japan		Europe *	
	1977	1987	1977	1987	1977	1987
Batteries	59.8	77.5	49.6	68.7	38.4	44.6
Cables	0.9	1.6	10.1	1.7	11.0	7.0

Source: Metallstatistik 1977 – 1987.

Lead batteries were responsible for 60 % of refined lead consumption in the Western world in 1987 (ca. 2.5×10^6 t). The battery market is by far the largest end use of lead. It has shown a steady growth rate of 6 % from 1984 to 1989, corresponding to the increase in the number of automobiles worldwide. Automotive batteries for starting, lighting and ignition (SLI), traction batteries, and stationary batteries account for 75, 10, and 15 % of total battery lead consumption, respectively.

SLI batteries represent the predominant use of lead. In 1987 about 160×10^6 batteries were used in new cars and for replacements in a world car population of over 500×10^6. The number of vehicles is expected to increase, and so should lead use in batteries. The content of lead and lead compounds in battery walls, grids, and coatings has been steadily reduced to improve performance, minimize weight, and extend lifetimes. This has contributed to much better operating economics. The vehicle battery market is obviously vulnerable to substitution by other elemental couples and chemistry, but so far no competition appears likely to have a serious impact. Other factors that could affect future SLI battery use are increasing power requirements of cars and haulage vehicles, which would demand more powerful batteries and the possible use of higher voltages.

Traction batteries are used to power electric vehicles which have low running costs and are quiet and pollution-free. The vehicles are commonly used in short-range commercial delivery applications, in airports, and as fork lifts. The heavy weight and limited capacity of the conventional lead – acid battery seriously restrict vehicle speed and operating range between charges. It is unlikely that the lead battery will power a successful design of passenger vehicle.

Stationary batteries are used for standby and emergency power supply. Besides emergency lighting, special applications involve computer installations, process control systems, and emergency power in aircraft and trains. The market is growing. A new market is developing for small, sealed cells used in safety and security systems and personal computers.

Pigments and Lead Compounds. After batteries, the next largest use of about 14 % of refined lead is in glass making, ceramic glazes, plastic stabilizers, and paints. Lead glass has desirable optical, electrical, and radiation shielding properties, and lead crystal glass in particular is in great demand (⟶ Glass). Although ceramic glazes for tiles, tableware, and fine china have declined in application because of concern about lead's toxicity, they remain a significant part of the compound market. Lead compounds used for stabilizing PVC against temperature and UV light are finding intensive competition from other, more environmentally acceptable stabilizers. The lead pigment market is now very small.

Semifinished Products. Rolled and extruded lead, mainly sheet and pipe, account for about 8 % of total lead use. Piping was formerly the greater part of this sector, but toxicity concerns and substitution by plastics and copper have reduced the market considerably. The use of lead sheet for roofing, restoration of old buildings, sound insulation, radiation shielding, and chemically resistant linings is now greater than that for piping and is growing steadily.

Cable Sheathing. A major area of lead use was in the protection of electrical and telecommunications cables, but this market has declined drastically since the early 1960s due to substitution by aluminum and plastics. Nevertheless, this application still accounts for about 5 % of total lead use, and there now appears to be a return to thin lead sheathing as a total moisture barrier in association with plastic sheathing.

Lead Alloys. Solders, type metal, bearing alloys containing lead still account for about 4 % of the lead consumption (⟶). Type metal usage has nearly disappeared, but the bearing metal market is still reasonable in spite of some substitution. Uses of lead-base solder are growing, as electronic products find increasing markets which outweigh the trend to miniaturization and inroads made by tin.

Gasoline Additives. In 1972 the use of tetraethyl lead for improving the octane rating of gasoline was nearly 400 000 t/a. Since then, this sector has declined dramatically by 70 %, principally in the United States. The reason has been the proscription of lead antiknock compounds by environmental legislation. The tetraethyl lead market, now 3 % of lead use, can be expected to disappear with the eventual departure of older vehicle engines that require leaded gasoline.

Shot and Ammunition. Shot and ammunition account for about 2 % of lead consumption and represent a steady market. Lead shot is used in alloying steel and brass to free machining metals, and for shotgun cartridges.

Miscellaneous. Uses that do not fall into the above categories account for about 4 % of lead use, and include products featuring the high density of lead such as wheel weights, yacht keels, ornamental items, stained glass, and massive radiation shielding.

Much work is being done by lead concerns to identify and develop new applications for the metal. Promising new uses include load levelling battery banks used by utilities or by major power consumers to reduce high-cost peak power consumption; lead containers for disposal of radioactive waste; and asphalt stabilizers for retarding road paving deterioration.

[Top of Page]

8. Economic Aspects

Charles A. Sutherland, Edward F. Milner, Herbert Teindl

8.1. Lead Concentrate Schedules

Most lead smelters operate with a concentrate supply from associated mines. A few " custom " smelters (e.g., at Hoboken) purchase essentially all feed materials on the open market. In rare cases a smelter will agree to " toll " a concentrate, whereby the concentrate supplier pays for the processing of his material as part of the smelter's overall charge, and receives the recovered metal for his own use.

Lead concentrate from the beneficiation of lead – zinc or lead – zinc – copper ores is the primary feed for blast furnace and flash smelters (see Section Ore Concentration). Smelters employing the Imperial Smelting process generally use mixed lead – zinc concentrates. Conventional lead concentrates consist of galena in a sulfide matrix; the lead content is usually well over 60 %. The concentrate may also contain zinc and iron sulfides; gangues such as silicon dioxide, calcium oxide, magnesium oxide, and aluminum oxide; and a number of minor metal impurities that may be partially or totally recovered and which may also cause smelting or refining problems. The price assigned to a concentrate by a smelter reflects its own priorities and the suitability of the concentrate for the operation, as regards its valuable components and impurities. Smelters reject concentrates with elements that adversely affect metallurgy or refining practice. Examples are rejection of a high-sulfur (low-lead) concentrate by a down-draft sintering operation or of a bismuthic concentrate by a refinery without a capability for bismuth removal and recovery.

In compounding the aggregate feed and in selecting concentrates for purchase, lead smelter metallurgists and ore buyers balance the inputs of all valuable and harmful elements to create a charge that can be handled effectively and consistently within the limits of the operating processes, and with maximum profit. The pattern is set by the major concentrate supplies, usually from in-company sources: other raw materials are obtained to fit objectives of output, quality, cost, and timing.

A lead smelter's purchase schedule for lead concentrates comprises identifications and rules that govern payments for certain components, penalties levied on the presence of others, occasional bonus payments or penalties for desirable or undesirable combinations, and a treatment charge designed to cover smelting and refining costs and allow for profit. Most smelters can make available a general or " open " schedule set out in sufficient detail to cover a wide range of raw materials, but this is applied only to small lots. Major longterm purchases are normally made on the basis of a negotiated schedule. The schedule of purchase terms also covers sampling, assay of constituents and moisture, settlement of disputes, reference metal prices for determination of paid values, currency exchange, escalation of costs and prices, and payment terms.

Through its applied schedules, a lead smelter always pays for lead, silver, and gold, often for copper and zinc, sometimes for bismuth, and very rarely for antimony, platinum, palladium, or indium. Lead payment is offered on about 95 – 97 % of the contained lead at a defined lead price. A blast furnace or flash smelter prefers lead content > 60 %, but an ISP smelter accepts lower lead content, particularly with associated substantial copper value. Silver and gold are routinely recovered at high efficiency by lead refineries, and are paid for at current prices subject to minimum deduction from the assayed content, reflecting the minor losses, and to a treatment charge.

A payment may be offered for contained zinc if the smelter processes high-zinc charges by slag fuming but additional costs for fluxes and fuel are assessed against the payment. The ISP smelters routinely pay for zinc subject to minimum deduction and a treatment charge. Iron is a major component of lead smelting slag and is of particular value in fluxing zinc, but may be present in excess of requirement and would then incur a modest penalty.

Most blast furnace and ISP smelters pay for copper, which is usually recovered in drossing as matte, subject to minimum deduction and treatment charge. ISP smelters can handle higher copper inputs than other lead smelters.

Arsenic is always heavily penalized under lead smelter schedule terms from levels as low as 0.05 %; this reflects the uncompensated problems arsenic creates in refining, hygiene, and environmentally acceptable disposal. Antimony is usually neither paid for nor penalized.

Bismuth's treatment in a lead smelter schedule depends on whether the refinery can separate and recover the metal comprehensively (as in electrolytic refining) or by pyrometallurgical debismuthizing at high unit cost. More often it would be a reason for rejection of the concentrate. Certain smelters can recover tin, indium, cadmium, and thallium in the sintering, drossing, and refining circuits but these elements are never paid for. Thallium may be the cause of rejection by an electrolytic

refinery and tin by an ISP zinc – lead smelter.

Lime and silica are desirable fluxes in lead smelting and are usually assigned minor credits in a lead schedule. Blast furnace smelters may penalize alumina for its deleterious effect on slag; ISP smelters can take higher aluminum oxide but are concerned with magnesium oxide content.

Other materials that are treated in lead smelters for lead and other values are scrap lead, scrap batteries, lead ashes and sludges, and zinc smelter leach residues. Metal and battery scrap are the normal feeds for secondary smelters under specific purchase terms. Zinc residues contain substantial lead and silver values in addition to substantial undissolved zinc, and are handled at high cost in additional fuel, fluxes, and slag fuming furnace operation in joint lead – zinc smelters such as the one at Trail.

8.2. Lead Statistics

World mine production of lead has been steady at (3.4 – 3.5)×10^6 t/a of contained lead since the early 1970s. Production since 1925 in thousands of tonnes is as follows:

1925. 1501
1950. 1686
1960. 2376
1970. 3433
1980. 3470
1985. 3581
1986. 3378
1987. 3389
1988. 3400
1989. 3319
1990. 3340
1991. 3331

The estimates of world lead resources shown in Table 1 represent a comfortable reserve against expected consumption requirements for the future, and there are excellent prospects for further economic discoveries.

Production (primary and secondary) and consumption of refined lead in the last ten years are shown in Table 7, and by area and trading bloc for 1987 in Table 8. About one-third of refined lead production is from recycled materials.

Table 7. World production (primary and secondary) and consumption of refined lead

Year	Production, ×10^6 t	Consumption, ×10^6 t
1977	5.388	5.466
1985	5.634	5.460
1986	5.464	5.551
1987	5.631	5.623

Source: Metallstatistik 1977 – 1987.

Lead ranked first in production among nonferrous metals in the first quarter of the twentieth century, but now ranks fourth after aluminum, copper, and zinc. This is due more to consumption growth for the other metals than to decline in lead use. Lead has suffered the loss of some major markets in pigments, water piping, and lead alkyls caused by legislation reflecting concern for its toxicity and environmental impact, from substitutions by plastics and aluminum, and the decrease in requirement for type metal. These losses now appear to have stabilized. They have been more than offset by the growth in production of lead batteries for automobile and transport use. The lead battery represents the dominant use of production and recycled lead and is the mainstay of the lead industry.

Of very considerable concern to the industry has been the slump in lead price, which reflects but far transcends the worldwide industrial recession in the first half of the 1980s (Table 9). The price of lead reached its lowest point in recorded history in terms of the real value of money in 1985. The period from 1982 to 1986 saw dismally inadequate returns and outright losses, with the abandonment of many producing mines and severe retrenchment or closure of smelting plants. Since the mid 1980s the price of lead has recovered by over 50 %. This has encouraged many lead producers to modernize or replace old smelting plants by the new flash-smelting technologies that are better able to meet the stringent hygiene and environmental regulations that govern plant operation.

Table 9. Annual average producer price of lead in the United States

Year	Price (U.S. cents/kg)
1978	74.28
1979	116.20
1980	93.73
1981	80.57
1982	56.38
1983	47.86
1984	56.40
1985	42.10
1986	48.74
1987	79.20
1988	81.08

9. Toxicology and Occupational Health

Hermann M. Bolt

Lead is one of the seven metals used in antiquity by the Eurasian civilization. Its uses were varied. Physicians prescribed various forms of lead to heal ailments ranging from constipation to infectious diseases such as the plague. Lead was also used to preserve or sweeten wine, for water pipes, cosmetics, and ceramic glazes.

The symptoms of lead poisoning have been recognized for centuries. HIPPOCRATES described lead colic in 370 B.C. and PLINY reported poisoning among lead workers in about 50 A.D. In 1700 RAMAZZINI [36] noted the illness of potters who worked with lead. In 1933 KEHOE et al. [37] brought to light the important consideration that lead is very widely found in the environment. Their studies showed that although lead is not an essential element for the body, a measurable amount exists in all adult body tissues and fluids.

There is considerable literature on the effects of lead, ranging from overt signs and symptoms of lead poisoning to subtle effects such as reduced intelligence quotient scores, behavioral effects, and impaired hearing. The relevance of these effects and the definition of lead exposure levels are subjects of extensive debate.

9.1. Sources of Lead Exposure

Many sources of lead exposure affect the workplace and the general population.

9.1.1. *Drinking Water*

Drinking water can be a significant contribution to lead intake, especially for young children.

Lead can enter the aquatic system through fallout and surface runoff, from natural sources, or from lead-lined tanks, lead pipes, and lead solder joints.

The lead content of drinking water is controlled in the EC and North America by water quality standards, and has been subject to revision [39].

Lead concentrations in drinking water exceeding 300 µg/L were reported in the 1980s [40]. Such high contents can be attributed to very soft water, low pH, and high temperature; for example, samples of soft, hot, or stagnant “first draw” water exposed to lead or lead in pipes usually have a high lead content.

9.1.2. *Atmosphere*

Worldwide natural lead emissions to the atmosphere from natural sources have been estimated to be 24×10^3 t/a, compared to $(350 – 450) \times 10^3$ t/a from anthropogenic sources. By far the greatest contribution comes from automotive lead emissions. A determined effort has been made in most countries to reduce the amount of allowable lead in gasoline. The lowering of lead in gasoline that started in the USA has been cited by the U.S. Center for Disease Control (CDC) as the major reason for the 37 % decrease in childrens’ blood lead levels, based on a nationwide survey conducted between 1976 and 1980 [42]. Another view was that the effect is attributable mainly to socioeconomic improvements. Lead emissions from industrial sites such as smelters and metal recovery operations also contribute to atmospheric lead. However, fallout from these sources is localized and is estimated to contribute only about 10 % of the overall lead emission. Ambient lead levels in the proximity of primary and secondary smelters can be significant. At El Paso, Texas, mean lead levels in 1971 ranged from 0.46 to 2.72 µg/m^3 with peak values as high as 22 µg/m^3 [43]. Sampling data from former Yugoslavia recorded peak levels in excess of 200 µg/m^3 [44]. Typical levels near point source areas are 0.1 – 1 µg/m^3 and for rural areas ≤ 0.1 µg/m^3. Community air quality criteria are set in the range of 0.5 – 2.0 µg/m^3 with a view to lowering these levels.

9.1.3. *Soil*

Natural soil can contain from 2 to 200 ppm lead and can be greatly influenced by anthropogenic sources. There are few standards for lead in soil; however, many countries have guidelines with suggested maximum levels of ca. 500 – 1000 ppm.

Lead-bearing dust can be especially dangerous to very young children because of a high level of ingestion through their play and eating habits. The concentration of lead in street dust and surface soil can be very high, especially if located near a major freeway. Soil samples from areas of Vancouver, Canada taken near heavy traffic areas were similar to samples taken 1.6 km from a large primary lead smelter complex (1545 and 1662 ppm, respectively) [45]. A survey of street dust in 77 Midwestern U.S. cities showed a mean lead content of 1600 ppm in residential areas and 2400 ppm in industrial areas [46].

9.1.4. *Diet*

Lead (mainly organic compounds) can enter the human body through the skin, by inhalation, or by ingestion. Ingestion in food is generally the major source of lead intake. Lead in the diet can come from numerous sources such as uptake of lead into plants; deposition onto vegetables; from soil or water; and from lead solder in canned goods.

Absorption of lead from the gastrointestinal tract by adults is estimated to be about 5 – 10 %, but 25 – 55 % by young children [47]. Ingestion of lead-based paint by children is still considered the most frequent cause of lead intoxication in the USA [48]. The amount of lead absorbed through the digestive system is greatly influenced by stress, fasting, and the solubility of the lead compound; for example, lead acetate is 25 times more soluble in intestinal fluid than lead sulfide [49].

9.1.5. *Occupational Exposure*

Workers employed in primary and secondary lead smelters, as well as in the production of lead metal and lead compounds, are exposed to lead absorption hazards. Because of the fine particle size of lead fume and its solubility, it can readily enter the respiratory system and be absorbed in the blood stream.

The workplace lead limits in the EC and North America have been tightened to the current range of 0.05 – 0.1 mg/m^3. The MAK value and the OEL recommended by the E.U. Scientific Committee for Occupational Exposure Limits (SCOEL) is 0.1 mg/m^3 and the TLV-TWA value (recommended by ACHIH) is 0.05 mg/m^3. This has been strong motivation for the development of new process technology, improvement of engineering controls, and stricter use of personal protective equipment by industry to reduce worker exposure.

9.2. Absorption and Excretion

Absorption of lead into the body is greatly affected by the size of the lead-containing particle and its solubility. Retention through the respiratory system is 20 – 60 % [50]. Particles of 0.1 – 1 µm are small enough to reach the alveoli, where absorption into the blood stream can take place; particles larger than 1 – 2 µm may be deposited in the nasopharangeal area, trachea, or bronchi and leave by swallowing or expectoration. Thus, fine lead fume has a much greater influence on a worker’s blood lead value than coarser dust.

Gastrointestinal absorption of lead is discussed in Section Sources of Lead Exposure. Absorption through the skin is not considered to be important for inorganic lead compounds, but organic lead compounds such as tetraethyllead and lead naphthenate are readily absorbed across the skin barrier.

Approximately 90 % of ingested lead is not absorbed and eliminated in the feces. Lead absorbed into the blood stream deports to soft tissue and gradually accumulates in bone. Some is excreted in urine. With consistent intake of lead, a steady state between lead concentrations in blood, soft tissue, and bone is established [51].

9.3. Effects

9.3.1. *Acute Effects*

The total average daily lead intake for adults in Western countries up to the 1980s has been estimated to be 150 – 300 µg, which is reflected in a blood lead level of 10 – 25 µg/dL. Blood taken from “normal” persons in 16 countries in the 1960s showed an average of 17 µg/dL. In the 1990s this has been reduced in Western countries to 5 – 10 µg/dL, mainly due to the introduction of unleaded gasoline.

9.3.2. *Hematologic Effects*

One of the more deleterious effects of lead is on blood and blood-forming tissue. Lead can inhibit almost all steps in the biosynthesis of hemoglobin [52].

9.3.3. *Neurological Effects*

In the early part of the 1900s, excessive prolonged exposure to lead was reflected in brain disease and muscle weakness in lead workers and children. Such extreme exposures have long been eliminated. Nowadays, the leading toxic effect of lead on the CNS in adults is impairment of performance in neurobehavioral tests. Most authors agree that a long-term Pb level of 40 µg/dL probably represents a NOAEL (no observed adverse effect level) or LOAEL (lowest observed adverse effect level) in this respect.

Other endpoints of lead toxicity such as the PNS are relevant only for exposure levels which are consistently higher.

Of great concern are neurological effects on infants. Neurobehavioral deficits have been correlated with lead content in teeth [53], and blood lead levels in children which were formerly considered to be acceptable are now being reviewed in many countries.

9.3.4. *Renal Effects*

The kidney is the major route for the excretion of lead that has been absorbed into the body, and it is also one of the organs affected by lead toxicity [54]. In most situations renal dysfunction occurring as a result of chronic lead exposure is reversible provided serious tissue damage has not occurred. However, irreversible renal damage may result from a prolonged, very high lead body burden. Hypertension can also follow.

9.3.5. *Reproduction Effects*

Toxic levels of lead can cause sterility in men, and miscarriages and spontaneous abortions in women. The fetus is especially vulnerable because lead can cross the placental barrier. There is considerable uncertainty concerning impairment of reproductive function by lead. Men with blood lead levels exceeding 60 – 70 µg/dL may have reduced sperm count and mobility [55]. In females, however, it is relevant that cognitive deficits of the offspring are dose-dependently associated with lead exposure. The question of reversibility of such deficits is not yet satisfactorily resolved. On the basis of the present data no definite NOAEL can be deduced, which strongly calls for a minimization of exposure.

9.3.6. *Carcinogenicity*

Lead and its compounds are under close international scrutiny with respect to its potential as cancer-causing agents. The IARC has listed inorganic lead compounds in Group 2B (agents that are possibly carcinogenic to humans), in generalization of observations on lead acetate and phosphate [56]. The observed experimental carcinogenicity of Pb salts is, in the first instance, directed towards the kidneys as the target tissue. Most probably, these effects are to a great extent based on the renal toxicity of high doses of Pb. Hence an OEL based on avoiding functional CNS alterations is expected also to protect against PNS and renal toxicity, including possible renal cancer development.

Similar conclusions may probably be drawn with respect to other systemic toxicities, e.g., on heme biosynthesis and blood pressure, although there is a discrepancy in opinions, and more research is needed in this direction.

9.4. Indices for Monitoring Lead Exposure

Biological monitoring of workers provides an assessment of overall exposure to a chemical or compound, and sets guidelines for the evaluation of potential health hazards. Two common indices for evaluation of overall lead absorption are outlined below.

9.4.1. *Lead in Blood*

Lead in blood is generally considered the best indicator of the lead concentration in soft tissue and is an effective means of assessing exposure to lead. Some investigators have been able to predict increases in blood lead after low lead exposures with some accuracy [57]. Blood lead levels of 60 – 70 µg/dL in male workers were considered acceptable up to the 1990s [58], but some authorities such as the WHO have proposed lower limits, of 40 µg/dL for males and 30 µg/dL for females. These biological limit values have also been recommended for occupationally exposed persons in the EU by SCOEL [60].

9.4.2. *Teeth and Hair*

Lead content in teeth, particularly dentine, has been used to assess exposure and measure psychological deficits in children

but is not practical for second-growth teeth. Hair has also been suggested as a method of evaluating lead absorption, but it is almost impossible to discern between intrinsic lead and that absorbed on the surface from external sources.

[Top of Page]

10. Control of Lead Emissions

Robert C. Kerby

The adverse effects of lead ingestion on the health of humans and animals (Chap. Toxicology and Occupational Health) make control of lead emissions a major operating challenge in all primary, secondary, and processing production industries. This overall problem has a dual focus:

1. The effect of emissions on in-plant atmospheric contamination and lead absorption by production workers.
2. The effect of plant emissions on ambient air lead levels and accumulative leady dust fallout on areas around the production site.

This challenge has long been part of the lead production industry, but since the 1970s improved diagnosis of biological problems related to lead and the resulting increased government regulatory pressure have greatly increased the demand for reduction of overall emission. Improved engineering controls and total process revisions are the broad approaches that have been taken to achieve compliance. Much progress has been made worldwide; however, the degree of success largely depends on the regulatory standards which have been set or proposed. In the United States, the proposed levels of 50 $\mu g/m^3$ for in-plant air and an annual mean of 1.5 $\mu g/m^3$ for lead in air outside the plant boundaries represent perhaps the most difficult industrial challenge.

10.1. In-Plant Lead Emissions

Engineering Controls. Assuming major process gas flows are handled by efficient dust removal equipment and discharged in high stacks, in-plant lead levels are mainly influenced by fugitive process emissions. Well-engineered ventilation systems are required to control dust and fume emissions from hot sinter or molten slags. The provision of effective ventilation is costly in terms of energy usage and capital cost.

Personal Respirators. The use of personal respirators by plant workers is almost universal practise to reduce respiratory lead intake from the plant atmosphere. The use of respirators is often construed as evidence of inadequate engineering control of fugitive emissions. Certainly the elimination of respirator use for most production jobs other than special maintenance work is a desirable objective, but, it is not being achieved in most plants at present. Personal hygiene habits are increasingly recognized as critical to controlling lead intake by workers. Measures such as provision of clean clothing, compulsory washing, no smoking or eating on the job, and clean eating facilities are common.

Process Revisions. The new oxygen smelting processes described in Section Direct Smelting Reduction Processes are attractive because they have inherent advantages for lead emission control. The traditional sintering and blast furnace method of lead production is a most difficult engineering challenge for achieving good control of in-plant emissions. The sinter operation involves large recirculating flows of hot, dusty, abrasive sinter requiring large ventilation volumes. Blast furnace reduction can be an erratic operation often troubled by a hot top and blowing and accompanying fugitive emissions from the gas collection system.

The new oxygen smelting processes have the following favorable characteristics:

1. Inherent lower process gas volume with oxygen usage giving less cleaning and reduced emissions
2. Recirculating loads requiring separate ventilation are minimized
3. Equipment is relatively compact and well sealed

The introduction of these new pyrometallurgical processes over the next one to two decades should have a major beneficial impact on the in-plant and ambient lead emission problems of today's primary lead smelters.

10.2. Ambient Lead Emissions

Ambient lead emissions originate from residual lead after cleaning of process and ventilation gas and general fugitive lead emissions. The accumulation of ambient lead fallout on vegetation eaten by cattle or the buildup of an objectional concentration of lead in the top soil is the most serious aspect of ambient emissions. The use of high-efficiency baghouses for cleaning process and ventilation gases, combined with curtailment of fugitive emissions of dust and fume from process equipment, roads, and stock yards, have made major reductions in ambient emissions at most primary and secondary lead smelters.

1. Introduction

Lead is one of the oldest known metals. Its use was known before 3000 BC. All early civilizations used lead extensively for ornamental and structural uses. The use of lead pipes for the transportation of water by the Romans, one of the early uses of lead, endures to the present.

The primary and most important mineral for recovery of lead is galena, PbS. Lead ores are found on every continent, usually in combination with zinc, copper, and silver. The United States is the leading lead-producing country followed by Canada and Australia. Total annual production of lead and lead alloys in 1987 was about 4.3×10^6 t. Recycling of lead scrap, mainly from batteries, lead sheet, and cable sheathing, provided 2.1×10^6 t.

About 40 % of lead is used as pure lead, lead oxides, or lead chemicals; the remainder is used in the form of lead alloys. The major uses of lead alloys are: lead acid batteries, ammunition, cable sheathing, building construction (sheets, pipes, and solders), bearings, gaskets, specialty castings, anodes, fusible alloys, shielding, and weights.

2. Properties of Lead and Lead Alloys

Lead is a heavy, soft, bluish gray metal which has a low melting point and a high boiling point. The density, malleability, lubricity, flexibility, and coefficient of thermal expansion are quite high. The elastic modulus, elastic limit, tensile and compression strength, hardness, and electrical conductivity are relatively low. Lead has excellent resistance to corrosion in a wide variety of media. Lead is easily alloyed with many other metals. Because lead alloys have low melting points, they can be cast into many shapes by using a variety of molding materials and casting processes.

Lead is very ductile and malleable, and can be fabricated into various shapes by rolling, extruding, forging, spinning, and hammering. The low tensile strength and very low creep strength of lead make it unsuitable for use without the addition of alloying elements. The major alloying elements used to strengthen lead are antimony, calcium, tin, copper, tellurium, arsenic, and silver. Minor alloying elements are selenium, sulfur, bismuth, cadmium, indium, aluminum, and strontium.

3. Lead – Antimony Alloys

3.1. Binary Lead – Antimony Alloys

Properties. Lead – antimony is the most widely used lead alloy. The phase diagram is shown in Figure 1 [3]. It contains a eutectic point at 11.1 wt % antimony and 252 °C. The solubility of antimony in lead decreases from 3.5 wt % at 252 °C to 0.25 wt % at 25 °C; therefore, the alloys are age hardenable. The grain structure of a typical cast lead – antimony alloy (see Fig. 2) consists of a lead matrix surrounded

10.1002/14356007.a15_237

by a network of antimony particles. The eutectic particles provide high-temperature strength. Addition of arsenic dramatically increases the rate of aging and final strength. Addition of tin increases the fluidity and, in combination with copper and arsenic, reduces the rate of oxidation of molten lead – antimony alloys [4].

Figure 1. Phase diagram of the lead – antimony system [3]
Reproduced from ref. [3] by permission of the publisher.

Figure 2. Grain structure of lead – antimony (5 wt %) alloy (magnification 160×)
White: antimony particles; Dark: lead matrix

The mechanical properties of lead – antimony alloys containing arsenic, tin, and copper are listed in Table 1. High-antimony alloys (> 3.5 wt % antimony) are strengthened primarily by the eutectic phase, whereas low-antimony alloys are strengthened by precipitation.

Lead – Acid Batteries (see also → Batteries, Chap. 4.). The major use of lead – antimony alloys is as grids, posts, and connectors for lead – acid batteries. The antimony eutectic prevents grid growth, retains the active material, and aids recovery from deep discharge. Deep-discharge industrial, load-leveling, and motive-power batteries utilize lead alloys containing 5 – 11 wt % antimony. Large tubular grids use 11 wt % antimony.

Antimony has one disadvantage for batteries. During use, antimony from the positive grid is oxidized, leaches into the electrolyte, and plates on the negative electrode. Antimony causes breakdown of water into hydrogen and oxygen during charging, leading to water loss. The amount of water lost is proportional to the amount of eutectic in the battery grid [5].

Automobile battery grids employ about 1 – 3 wt % antimony – lead alloys. Hybrid batteries use low antimony (1.6 – 2.5 wt %) alloys for the positive grids and nonantimony alloys for the negative grids to give reduced or no water loss. The posts and straps of virtually all lead – acid batteries are made of alloys containing about 3 wt % antimony.

Although low antimony content decreases water loss, it presents problems in casting thin grids. Alloys having less than 3.5 wt % antimony have reduced fluidity and increased volume shrinkage. The grain size increases with decreasing antimony content, as seen in Figure 3. The large columnar grains of low-antimony alloys are shown in Figure 4. To prevent formation of large grains, nucleants are added to lead – antimony alloys. Small amounts of sulfur, copper, or selenium serve as sites for growth of lead crystals during solidification and produce fine, rounded grain structures which are resistant to cracking [4–7]. By using nucleants, fine-grained structures, such as that shown in Figure 5, can be produced in cast alloys independent of the antimony content. The molten metal must be kept at a temperature high enough to assure complete solubility of the nucleants prior to casting the alloy. The United States uses primarily copper and sulfur as nucleants, while Europe and Asia use selenium. At very low antimony contents (1.0 – 1.6 wt %) selenium is used.

Ammunition. Lead shot is produced by dropping molten lead – antimony alloys containing 0.5 – 8 wt % antimony through holes in pans into water. The shot alloys contain arsenic in an amount equal to about 20 – 30 wt % of the

Table 1. Mechanical properties of lead – antimony alloys

Antimony content, wt %	Yield strength, MPa, after aging		Tensile strength, MPa	Elongation, %
	1 day	30 days	30 days	30 days

antimony content. Arsenic permits the molten drop of lead to become round during freefall. Tin and cadmium produce elongated shot if present; therefore, they are restricted to less than 0.0005 wt %. Shot up to 5.8 mm in diameter is dropped from towers; larger shot must be cast in molds. Lead – antimony (0.5 – 3.0 wt %) alloys are used for cast or swagged bullets.

Cable Sheathing. Lead – antimony alloys containing 0.5 – 1.0 wt % antimony are used for cable sheathing as well as lead – copper and lead – tin – arsenic alloys. Antimony-containing alloys are used when higher strength and resistance to vibration is required. British standard BS-801 alloy B contains 0.85 wt % antimony. Lead – antimony alloys having 0.6 wt % or less antimony can be continuously extruded, are impervious to oil and moisture, and remain pliable indefinitely. Lead – antimony (1.0 wt %) is generally used as sleeves for cable splices.

Anodes. Lead – antimony (6 – 10 wt %) alloys containing 0.5 – 1.0 wt % arsenic have been used widely as anodes in copper, nickel, and chromium electrowinning and metal-plating processes. Lead – antimony anodes have high strength and develop a corrosion-resistant protective layer of lead dioxide during use. Lead – antimony anodes are resistant to passivation when the current is frequently interrupted.

Wrought Lead – Antimony. Wrought lead – antimony alloys are weaker and have higher creep rates than cast lead – antimony alloys, but have greater strength than lead – copper

alloys; they can be easily fabricated into most lead products. Because of their excellent resistance to corrosion by a variety of chemicals, lead – antimony (4 – 8 wt %) alloys are used for tank linings, pumps, valves, and heating and cooling coils, particularly where sulfuric acid or sulfate solutions are handled at elevated temperature. Arsenic is generally added to increase resistance to creep at elevated temperature.

3.2. Lead – Antimony – Tin Alloys

Lead – antimony – tin alloys are used for printing, bearings, solders, slush castings, and specialty castings. These alloys have low melting points, high hardness, and excellent high-temperature strength and fluidity.

Printing alloys generally contain more than 11 wt % antimony and 3 – 14 wt % tin. Typical alloys (see Table 2) have low melting points and high hardness for wear resistance in printing. Replication of mold detail is particularly important.

Table 2. Printing alloys

Process	Composition, wt %			Liquidus, °C	Solidus, °C	Brinell Hardness
	Sn	Sb	Pb			
Linotype	4	11.5	84.5	243	239	22
Electrotype	3	3	94	299	245	14
Stereotype	5	14	81	256	240	23
Monotype	7	16.5	76.5	275	240	26
Foundry type	14	24	62	318	240	32

Excellent antifriction properties and good hardness makes lead – antimony – tin alloys suitable for journal bearings, bushings, and sleeve bearings. The alloys contain 9 – 15 wt % antimony and 1 – 20 wt % tin. They also contain copper and arsenic, which improve compression, fatigue, and creep strength, important in bearings. Lead – antimony – tin bearing alloys are listed in ASTM B23-83 [8].

Specialty castings include belt buckles, trophies, casket trim, miniature figures, and holloware. Slush castings are produced by pouring an alloy into a mold, permitting a given thickness to solidify, and pouring out the remaining liquid to produce a hollow, light, high-detail casting. The near-eutectic lead alloy, containing 11 wt % antimony, 1 wt % tin, and 0 – 0.5 wt % arsenic, has a low melting point which permits silicon rubber molds to be used in spin-casting processes.

Low-antimony (2 – 5 wt %), low-tin (2 – 5 wt %) lead alloys are used for automobile body solder. Special lead – antimony alloys containing 1 – 4 wt % antimony are used for wheel-balancing weights, battery cable clamps, and collapsible tubes.

4. Lead – Calcium Alloys

Lead – calcium alloys are replacing lead – antimony alloys for many applications. Most U.S. original-equipment automotive batteries are constructed of lead – calcium, whereas most U.S. replacement batteries utilize lead – calcium alloys for the negative grids and lead – antimony alloys for the positive grids. Lead – calcium is used worldwide for standby power, submarine, and specialty sealed batteries. Lead – calcium alloy batteries do not require addition of water and can therefore be sealed. Lead – calcium alloy is used for electrowinning anodes, cable sheathing, sleeving, specialty boat keels, and lead alloy tapes.

4.1. Binary Lead – Calcium Alloys

The lead – calcium phase diagram is shown in Figure 6 [3]. The phase diagram is a peritectic with a peritectic temperature of 328.3 °C. The maximum solubility of calcium is 0.10 wt % at 328.3 °C and rapidly decreases to 0.02 wt % at 200 °C and 0.01 wt % at 25 °C. The large decrease in solubility with decreasing temperature permits precipitation strengthening of binary lead – calcium alloys by the compound Pb_3Ca [*12049-58-0*]. This compound is also formed in molten alloys containing more than 0.07 % calcium. Figure 7 shows the Pb_3Ca primary particles formed by solidification of an alloy containing 0.14 wt % calcium. The Pb_3Ca particles can act as nucleants and produce fine-grained microstructures.

Below 0.10 wt % calcium the alloys solidify into a cellular, dendritic grain structure (Fig. 8) [9]. Impurities segregate to the intercellular boundaries, causing them to be accented in

Figure 6. Phase diagram of the lead – calcium system [3] Reproduced from ref. [3] by permission of the publisher.

Figure 7. Grain structure of lead – calcium (0.14 wt %) alloy (magnification 160×); the dark spots are Pb_3Ca particles

Figure 8. Grain structure of freshly cast lead – calcium (0.07 wt %) alloy (magnification 160×)

Figure 9. Grain structure of lead – calcium (0.07 wt %) alloy aged for seven days, showing the serrated grain boundaries (magnification 160×)

the microstructure. Reverse segregation causes some areas of the casting to contain 0.10 wt % calcium regardless of the original calcium content of the melt. Precipitation of calcium occurs by a discontinuous precipitation reaction [10]. In this reaction, grain boundaries move through the matrix, the original cast grain is destroyed, and the characteristic serrated grain boundaries of lead – calcium alloys seen in Figure 9 are produced [11]. The calcium content and the rate of grain boundary movement determine the final grain size and shape.

Lead – calcium (0.04 %) alloy, used as cable sheaths and sleeves for cable splices, is significantly stronger and has greater creep resistance than lead – copper (0.06 wt %) or lead – antimony (1 wt %). Table 3 compares the mechanical properties of lead – calcium to these alloys and to pure lead. The lead – calcium alloys have outstanding creep and fatigue resistance and relatively good ductility. Aging after production may cause a permanent set and difficulty in uncoiling; hence, lead – calcium is used primarily in straight lengths or as sleeves.

The main use of binary lead – calcium alloys is for the grids in large, stationary stand-by power batteries. These batteries use alloys containing 0.03 – 0.07 wt % calcium. The alloy has

sufficient strength for the application, but it is used principally because of its resistance to self-discharge and because it reduces water loss. The grids are large grained and resistant to growth.

Table 3. Mechanical properties of pure lead and lead alloys

Property	Composition, wt %			
	Pb, 100	Cu, 0.06	Sb, 1	Ca, 0.04
Tensile strength, MPa	12.2	17.4	20.9	27.9
Elongation, %	55	55	35	35
Fatigue strength, MPa	2.75	4.90	6.28	9.02

Reactivity of Lead-Calcium Alloys. Precise control of the calcium content is required to control the grain structure, corrosion resistance, and mechanical properties of lead – calcium alloys [12], [13]. Calcium reacts readily with air and other elements such as antimony, arsenic, and sulfur to produce oxides or intermetallic compounds. In these reactions, calcium is lost and suspended solids reduce fluidity and castibility. The very thin grids that are required for automotive batteries are difficult to cast from lead – calcium alloys.

A rapid method to determine the calcium content of lead alloys is a liquid-metal titration with lead – antimony (1 %) [14]. The end point is indicated by a gray oxide film pattern on the surface of a solidified sample of the metal when observed at a 45° angle to a light source. The basis for the titration is the reaction between calcium and antimony. The percentage of calcium in the sample can be calculated from the amount of antimony used. If additional calcium is needed in the alloy, the melt is sweetened with a lead – calcium (1 wt %) master alloy.

4.2. Lead – Calcium – Aluminum Alloys

Lead – calcium alloys can be protected against loss of calcium by addition of aluminum [15]. Aluminum provides a protective oxide skin on molten lead – calcium alloys. Even when scrap is remelted, calcium content is maintained by the presence of 0.02 wt % aluminum. Alloys without aluminum rapidly lose calcium, whereas those that contain 0.03 wt % aluminum exhibit negligible calcium losses, as shown in Figure 10 [16]. Even with less than optimum aluminum levels, the rate of oxidation is lower than that of aluminum-free alloys.

Figure 10. Effect of aluminum on loss of calcium
a) With 0.03 wt % aluminum; b) Without aluminum

Producing lead – calcium – aluminum alloys is difficult. Calcium and aluminum can be added simultaneously to lead using a calcium (73 wt %) – aluminum (27 wt %) master alloy [17]. With this method, the calcium and aluminum contents can be precisely controlled. Pressed pellets of metallic aluminum and metallic calcium are also used.

Lead alloys containing 0.09 – 0.15 wt % calcium and 0.015 – 0.03 wt % aluminum are used for the negative battery grids of virtually all lead – acid batteries in the United States and are also used in Japan, Canada, and Europe. If the molten alloy is held at too low a temperature, the aluminum precipitates from solution, rises to the surface of the molten alloy as finely divided aluminum particles, and enters the dross layer atop the melt.

4.3. Lead – Calcium – Tin Alloys

The addition of tin to lead – calcium alloys enhances the mechanical and electrochemical properties but reduces the rate of hardening

compared to binary alloys. The positive-grid alloys for maintenance-free lead – calcium batteries contain 0.3 wt % or more tin and also aluminum.

Cast lead – calcium – tin alloys usually contain 0.06 – 0.11 wt % calcium and 0.3 wt % tin. They have excellent fluidity, harden rapidly, have a fine grain structure, and are resistant to corrosion. Table 4 lists the mechanical properties of cast lead – calcium – tin alloys and other alloys.

Wrought lead – calcium – tin alloys contain more tin, have higher mechanical strength, exhibit greater stability, and are more creep resistant than the cast alloys. Rolled lead – calcium – tin alloy strip is used to produce automotive battery grids in a continuous process [18]. Table 5 lists the mechanical properties of rolled lead – calcium – tin alloys, compared with copper – lead and lead – antimony (6 wt %) alloys.

Lead Anodes. A major use for lead – calcium – tin alloys is lead anodes for electrowinning. The lead – calcium anodes form a hard, adherent lead dioxide layer during use, resist corrosion, and greatly reduce lead contamination of the cathode. Anodes produced from cast lead – calcium (0.03 – 0.09 wt %) alloys have a tendency to warp due to low mechanical strength and casting defects.

Wrought lead – calcium – tin anodes have replaced many cast lead – calcium anodes [19]. Superior mechanical properties, uniform grain structure, low corrosion rates, and lack of casting defects result in increased life for wrought lead – calcium – tin anodes compared to other lead alloy anodes.

5. Lead – Tin Alloys

The lead – tin phase diagram is shown in Figure 11 [3]. It exhibits a eutectic point at 61.9 wt % tin and 183 °C. The solid solubility of tin at 183 °C is 19 wt %, decreasing to 1.9 wt % at 25 °C.

Solders. The major use of lead – tin alloys is as solders for sealing and joining metals. Solders range in composition from 30 to 98 wt % lead, the remainder being tin. Lead – tin (2 wt %) solder is used to seal the side seams of steel (tin) cans. Addition of 0.5 wt % silver to the alloy significantly improves the creep strength which is essential in pressurized cans. Pre-tinned cans allow the use of low-tin solder. High-speed manufacturing of cans requires an alloy with a very narrow freezing range.

Lead – tin alloys containing 40 – 50 wt % tin are used for general purpose soldering. Low-melting lead – tin solder with 63 wt % tin is used for electronic soldering, particularly for printed circuit boards. Lead alloys with 15 – 30 wt % tin are used for soldering automobile radiators and other types of heat exchanger. A lead alloy containing 2.5 wt % tin and 0.5 wt % silver is used when high-temperature fatigue and creep strengths are required, for example, in soldered connections in heat exchangers. Solders with 35 – 40 wt % tin have a wide plastic range and are used for wiping lead joints. Sometimes, 0.5 – 2.0 wt % antimony is added to improve mechanical properties. Antimony contents of 0.2 – 0.5 wt % prevent brittle phase transformations at low temperatures.

Figure 11. Phase diagram of the lead – tin system [3]
Reproduced from ref. [3] by permission of the publisher.

Corrosion Protection. Lead – tin alloys are used for corrosion resistant coatings on steel and copper. Terne steel is steel sheet coated with a lead alloy containing 15 – 20 wt % tin. This alloy contains sufficient tin to alloy with the surface of the steel. Terne sheets are produced flat or coiled, carrying different coating weights. These coated sheets are used for radio and television chassis, roofs, fuel tanks, air filters, oil filters, gaskets, metal furniture, gutters, and downspouts. Terne

steel has good corrosion resistance, draws well, is relatively cheap, and offers a good base for painting.

A similar coating, containing 4 wt % tin, is applied to copper sheet and is used primarily for building flashings (ASTM B101-83) [8]. Other lead – tin alloys, usually with 50 wt % tin, are applied as coatings to steel and copper electronic components for corrosion protection, appearance, and ease of soldering. Lead – tin alloys can be built up easily to any desired thickness by electroplating from a fluoroborate solution. Electroplated coatings are not recommended for corrosion protection because they tend to be porous.

Tin is also used as an alloying element in lead – antimony alloys to improve fluidity and to prevent drossing; in lead – calcium alloys to improve mechanical properties and enhance electrochemical performance; in lead – arsenic alloys to maintain a stable composition; and as an additive to low-melting alloys.

Lead – tin (1.8 – 2.5 wt %) is used as a cable sheathing alloy (BS 801 alloy A and DIN 17 640). Tin is generally added to lead – arsenic cable alloys in small amounts. The arsenic alloys have excellent creep resistance and mechanical properties, but are unstable and lose arsenic readily by oxidation. The addition of small amounts of tin (0.10 – 0.20 wt %) eliminates arsenic loss. Lead alloys having 0.4 wt % tin and 0.15 % cadmium, which are used for cable sheathing, do not age harden, show excellent corrosion and creep resistance, and are very ductile.

6. Lead – Copper Alloys

Copper is an alloying element as well as an impurity in lead. The lead – copper system has a eutectic point at 0.06 % copper and 326 °C. In lead refining, the copper content can thus be reduced to about 0.08 % merely by cooling. Further refining requires chemical treatment. The solubility of copper in lead decreases to about 0.005 % at 0 °C.

High-copper lead alloys generally contain 60 – 70 % copper. The mechanical properties of sand-cast copper – lead alloys are shown in Table 6. The high-copper alloys are difficult to cast and are susceptible to extensive segregation. Cast lead – copper (60 – 70 wt %) alloys are used as bearings and bushings for high-temperature service. The cast alloys have been recently replaced by sintered copper powder products infiltrated with lead to produce more uniform distribution of the lead.

Only lead alloys containing copper below 0.08 % have practical applications. Lead sheet, pipe, cable sheathing, wire, and fabricated products are produced from lead – copper alloys with copper contents near the eutectic composition. Lead – copper alloys in the range 0.03 – 0.08 wt % copper are covered by many speci-

fications: ASTM B29-79 (- 84) [8], QQL 171 (United States), BS 334, HP2 Type 11 (Canada), DIN 1719, and AS 1812 (Australia). Lead–copper alloys are specified because of superior mechanical properties, creep resistance, corrosion resistance, and high-temperature stability.

Table 6. Mechanical properties of sand-cast copper–lead alloys

Property	Lead Content	
	30 wt %	40 wt %
Tensile strength, MPa	55.8–62.8	52.3–59.2
Elongation, % in 50.8 mm	6–8	6–8
Compressive strength, MPa	20.9	17.5
Brinell hardness	23–33	20–30

Lead–copper alloys are the primary material used in the continuous extrusion of cable coverings for the electrical power cable industry in the United States. Other alloys, containing tin and arsenic as well as copper, have also been developed for cable sheathing in the United States to provide higher fatigue strength.

Extruded or rolled lead–copper alloys contain a uniform dispersion of copper particles in a lead matrix. Because the solid solubility of copper in lead is very low, copper particles in the matrix remain stable up to near the melting point of lead, maintaining uniform grain size even at elevated temperature.

Copper-containing lead alloys undergo less corrosion in sulfuric acid or sulfate solutions than pure lead or other lead alloys. The uniformly dispersed copper particles give rise to local cells in which lead forms the anode and copper forms the cathode. Through this anodic corrosion of the lead, an insoluble film of lead sulfate forms on the surface of the lead, passivating it and preventing further corrosion. The film, if damaged, rapidly reforms.

Lead–copper alloys are also used as tank linings, tubes for acid-mist precipitators, steam heating pipes for sulfuric acid or chromate plating baths, and lead sheathing for roofs.

7. Lead–Silver Alloys

Silver readily forms alloys with lead. Lead is often used as a base metal solvent for silver-recovery processes. The lead–silver system is a simple eutectic with the eutectic point at 2.5 wt % silver and 304 °C. The solid solubility of silver in lead is 0.10 wt % at 304 °C, dropping to less than 0.02 wt % at 20 °C.

Lead–silver alloys show significant age hardening when quenched from elevated temperature. Because of the pronounced hardening which occurs with small amounts of silver, the content of silver as an impurity in pure lead is restricted to less than 0.0025 wt % in most specifications. Small additions of silver to lead produces high resistance to recrystallization and grain growth.

The major uses for lead–silver alloys are as anodes and high-temperature solders. Only lead–silver alloys containing less than 6 wt % silver are used commercially. Lead alloys containing 0.75–1.25 wt % silver are used as insoluble anodes in the electrowinning of zinc and manganese. Some zinc refineries have reduced the silver content of the anodes to as low as 0.25 wt %. Lead–calcium–silver anodes are also used for zinc electrowinning. Silver promotes the formation of very hard, dense, electrically conducting layers of lead dioxide on the surface of the anode.

Silver reduces the oxygen evolution potential at the anode, which reduces the rate of corrosion and decreases lead contamination of the cathode. Lead–antimony–silver alloy anodes are used for the production of thin copper foil for use in electronics. Lead–silver (2 wt %), lead–silver (1 wt %)–tin (1 wt %), and lead antimony (6 wt %)–silver (1–2 wt %) alloys are used as anodes in cathodic protection of steel pipes and structures in fresh, brackish, or sea water. The lead dioxide layer is not only conductive, but also resists decomposition in chloride environments. Silver-free alloys rapidly become passivated and scale badly in sea water.

Silver is also added to the positive grids of lead–acid batteries in small amounts (0.005–0.05 wt %) to reduce the rate of corrosion.

Lead–silver alloys are used extensively as soft solders; these contain 1–6 wt % silver. Lead–silver solders have a narrower freezing range and higher melting point (304 °C) than conventional solders. Solders containing 2.5 wt % silver or less are used either as binary alloys or combined with 0.5–2 wt % tin. Lead–silver solders have excellent corrosion resistance. The composition of lead–silver sol-

ders is listed in ASTM B-32-87 (solder alloys) [9].

8. Lead – Tellurium Alloys

Tellurium is often used in lead alloys when high mechanical strength at minimal alloy content is required. It is used for pipes and sheets, shielding for nuclear reactors, and cable sheathing. Lead alloys containing 0.035 – 0.10 wt % tellurium generally also contain copper in amounts of 0.03 – 0.08 wt %. The U.S. Federal Specifications QQL-201F and ASTM B-749-85 [8] cover the use of wrought lead – tellurium alloys. Lead – tellurium alloys for cable sheathing are specified by DIN 17 640.

Cold-rolled alloys of lead with 0.06 wt % tellurium often attain ultimate tensile strengths of 25 – 30 MPa. High mechanical strength, excellent creep resistance, and low levels of alloying elements have made lead – tellurium alloys the primary material for nuclear shielding for small reactors such as those aboard submarines. The alloy is self supporting and does not generate secondary radiation.

Wrought or extruded lead – tellurium (0.035 – 0.10 wt %) alloys produce extremely fine grains. The binary alloy is, however, susceptible to recrystallization. The addition of copper or silver reduces grain growth and retains the fine grain size. Since tellurium is a poison for sealed lead – acid batteries, the tellurium content of lead and lead alloys used for such purposes is usually restricted to less than 2 ppm.

9. Low-Melting Alloys

Lead alloys with large amounts of bismuth, tin, cadmium, and indium that melt at relatively low temperatures (10 – 183 °C) are known as fusible or low-melting alloys. The specifications of many of these alloys are listed in ASTM B 774-88 [8].

These alloys are used as fuses, sprinkler system alloys, foundry pattern alloys, molds, dies, punches, cores, and mandrels where the low-melting alloy is often melted out of a mold. The alloys are also used as solders, for the replication of human body parts, and as fillers for tube bending. Lead – indium alloys are often used to join metals to glass.

10. Reactive Lead Alloys

Strontium – lead alloys behave similarly to lead – calcium alloys in terms of mechanical properties and performance. Lead – strontium (0.08 – 0.20 wt %) alloys, also containing aluminum, have been used as battery grid alloys. They have excellent fluidity, harden rapidly, and have excellent resistance to corrosion. However, these alloys over-age rapidly, resulting in significant loss of mechanical strength within several days. The addition of 1 wt % or more of tin is required to resist over-aging. The high cost of lead – strontium alloys compared to lead – calcium alloys has restricted their use. Lead – strontium – tin alloys are used as anodes for copper electrowinning.

Lead – lithium and lead – lithium – tin alloys have been proposed as alloys for lead – acid battery grids because of very rapid aging and very high mechanical properties. These alloys are, however, susceptible to grain boundary corrosion. Lead – lithium alloys containing strontium, barium, and calcium have been used for bearings. The high melting point and the retention of mechanical properties and stability at high temperature make these alloys particularly attractive for bearings. The addition of aluminum to prevent oxidation permits casting at high temperatures without oxidation.

11. Occupational Health and Safety

Because of the toxicity of lead, special care must be taken when working with lead alloys. Lead and its inorganic compounds are neurotoxins which may produce peripheral neuropathy. For an overview of the effects of lead exposure, see Occupational Exposure to Lead, Appendix A (29CFR 1910.1025) [20].

Most lead alloys are first melted during processing. The melting or fusing of lead alloys may generate lead oxides, drosses, or fumes which can present a health hazard. The major routes for absorption of lead metal are inhalation and ingestion. Inhalation can be avoided by use of

ventilators and respirators where the exposure is above the permissible exposure limit (PEL) or the threshold limit value (TLV) specified by OSHA (United States) or other local, municipal, or federal regulations. These limits vary considerably by industry and country but generally consist of a PEL of ca. 50 – 200 µg/m^3 of lead in air, and lead levels of 50 – 100 µg/dL in whole blood.

Coveralls or other full-body clothing should be worn when working with lead alloys and properly laundered after use. Hard hats, safety glasses, safety boots, and other safety equipment should be worn as appropriate for the industrial environment where the lead alloys are used. Hands, face, neck, and arms should be washed before eating or smoking.

Lead – antimony or lead – arsenic alloys must not be mixed with lead – calcium(aluminum) alloys in the molten state. Addition of lead – calcium – aluminum alloys to lead – antimony alloys results in reaction of calcium or aluminum with the antimony and arsenic to form arsenides and antimonides. The dross containing the arsenides and antimonides floats to the surface of the molten lead alloy and may generate poisonous arsine or stibine if it becomes wet. Care must be taken to prevent mixing of calcium and antimony alloys and to ensure proper handling of drosses.

If the temperature of a molten lead – calcium(tin) – aluminum alloy is not kept sufficiently high, finely divided aluminum particles may precipitate and float to the top of the melt. They may become mixed with oxides of lead in the dross. The finely divided aluminum particles can react violently with the oxides in the dross if ignited. Ignition can occur if attempts are made to melt or "burn" the dross away from areas of buildup with a torch. The oxides in the dross can supply oxygen for the combustion of aluminum once ignited.

Despite the benefits of lead and lead alloys, the use of these materials is declining rapidly, due primarily to environmental health and safety factors. For many years, lead alloys have been the material of choice for many corrosive environments, but they are now being replaced by stainless steel, plastics, and exotic metals. The toxic nature of lead requires special precautions and handling not necessary with other materials. These requirements have reduced the usage of lead alloys.

1. Introduction

Lead is one of the oldest known metals, dating from about 3000 B.C. (→ Lead). The Romans used lead extensively for water pipes, while in ancient Egypt, lead compounds were employed for glazing pottery and ornamental objects, a purpose for which they are still used today. Now, the largest single use of lead compounds, mainly lead oxide, is for the manufacture of lead – acid storage batteries. Other industrially important uses of lead compounds range from antiknock additives in gasoline to lead crystal glasses and stabilizers for plastics during thermal processing.

2. Lead Salts and Oxides

Lead is an amphoteric element, which forms lead salts with acids as well as metal salts of plumbic acid with alkalies. Lead forms many salts, oxides, and organometallic compounds. Although lead has four electrons in its outer (or valence) shell, the usual valence of lead is + 2, rather than + 4, because of the reluctance of its two 6 *s* electrons to ionize. Also, the divalent plumbous ion differs from the other group 14 divalent ions, such as the stannous ion (Sn^{2+}), in that it does not have reducing properties.

Many inorganic lead compounds have two or more crystalline forms with different properties. As a result, the oxides and sulfide of divalent lead often appear colored because of their state of crystallization. Thus, pure, tetragonal α-PbO is red; orthorhombic β-PbO is yellow; and crystals of lead sulfide, PbS, have a black, metallic luster. On the other hand, the carbonates, sulfates, nitrates, and halides (except for the yellow iodide) are colorless.

Highly crystalline basic lead salts, both anhydrous and hydrated, are readily formed. For example, tetrabasic lead sulfate [*52732-72-6*], $4\,PbO \cdot PbSO_4$, and the tribasic lead sulfate hydrate [*12202-17-4*], $3\,PbO \cdot PbSO_4 \cdot H_2O$, are prepared by boiling suspensions of lead oxide and lead sulfate in water. Moreover, complex mixed salts, such as white lead, $2\,PbCO_3 \cdot Pb(OH)_2$, are readily formed.

Most lead compounds are derived from pig lead (refined metal),usually via conversion to lead monoxide (PbO), commonly known as litharge. In general, lead compounds may be formed by the reaction of a slurry of litharge and the appropriate acid, by the reaction of a solution of a lead salt with an acid, or by fusion of litharge with the appropriate metal oxide. In the latter case, for example, the ease with which lead monoxide combines with silicon dioxide to form a low-melting silicate has been utilized in the ceramics industry for producing glasses and glazes.

2.1. Lead Acetates

Lead reacts readily with acetic acid to form four different lead acetate compounds: anhydrous, basic, trihydrate, and tetraacetate. Some physical properties of the lead acetates are summarized in Table 1.

Anhydrous lead acetate, plumbous acetate, $Pb(C_2H_3O_2)_2$, is a white, crystalline solid that

Table 1. Physical properties of lead acetates [8]

Compound	CAS registry no.	M_r	*mp*, °C	ϱ, g/cm^3	Solubility, g/100 mL H_2O (t, °C)
$Pb(C_2H_3O_2)_2$	[*301-04-2*]	325.29	280	3.25	44.3 (20), 221 (50)
$2\,Pb(OH)_2 \cdot Pb(C_2H_3O_2)_2$	[*1335-32-6*]	807.69	75 (dec. 200)		6.25 (15), 25 (100)
$Pb(C_2H_3O_2)_2 \cdot 3\,H_2O$	[*6080-56-4*]	379.33	75 (dec. 200)	2.55	45.6 (15), 200 (100)
$Pb(C_2H_3O_2)_4$	[*546-67-8*]	443.38	175	2.228	dec.

is very soluble in water. It is made by dissolving lead monoxide or lead carbonate in concentrated acetic acid. Solutions of lead acetate are often used to prepare other lead salts.

Basic lead acetate, lead subacetate, $2\,Pb(OH)_2 \cdot Pb(C_2H_3O_2)_2$, is a heavy white powder that is very soluble in water and soluble in ethanol. It is prepared by dissolving lead monoxide in dilute acetic acid. Basic lead acetate is used for sugar analysis.

Lead acetate trihydrate, sugar of lead, $Pb(C_2H_3O_2)_2 \cdot 3\,H_2O$, is a white, monoclinic crystalline solid having a refractive index (along the β axis) of 1.567. It is very soluble in water, but insoluble in ethanol. Lead acetate trihydrate is prepared by dissolving lead monoxide in hot dilute acetic acid; large, long crystals separate upon cooling. Although the crystals are intensely sweet, they are poisonous. Lead acetate trihydrate is the usual commercial form of lead acetate and it is available in technical and reagent grades. It is used to make other lead compounds (for example, basic lead carbonate, lead chromate, and lead salts of higher fatty acids), as a mordant for cotton dyes, as a water repellant, and as a processing agent in the cosmetic, perfume, and toiletry industries.

Lead tetraacetate, plumbic acetate, $Pb(C_2H_3O_2)_4$, is a colorless, monoclinic crystalline solid that is soluble in chloroform and in hot acetic acid, but decomposes in cold water and in ethanol. Lead tetraacetate is prepared by adding warm, anhydrous, glacial acetic acid to red lead (Pb_3O_4) and subsequently cooling the solution. It is available in laboratory quantities as colorless to faintly pink crystals stored under glacial acetic acid. Lead tetraacetate is often used as an oxidizing agent in organic syntheses because it is highly selective in cleaving vicinal glycols. It also readily cleaves α-hydroxy acids, such as oxalic acid, at room temperature. Another use is for the introduction of acetoxy groups in organic molecules [9].

2.2. Lead Carbonates

Lead carbonate [*598-63-0*], $PbCO_3$, M_r 267.21, ϱ 6.6 g/cm^3, forms colorless orthorhombic crystals having refractive indices of 1.804, 2.076, and 2.078. It is slightly soluble in cold water (1.1 mg/L at 20 °C), is soluble in acids and alkalies, but is insoluble in aqueous ammonia and ethanol. Lead carbonate is produced by passing carbon dioxide into a cold dilute solution of lead acetate, or by shaking a suspension of a lead salt (less soluble than the carbonate) with ammonium carbonate at low temperature to avoid formation of basic lead carbonate. Lead carbonate is used in the catalytic polymerization of formaldehyde to give high molecular mass crystalline poly(oxymethylene) [10], to improve the bonding of polychloroprene to metals in wire-reinforced hoses [11], as a component of high-pressure lubricating greases [12], and as a lubricant and stabilizer for poly(vinyl chloride) [13].

Basic lead carbonate [*1319-46-6*], white lead, $2\,PbCO_3 \cdot Pb(OH)_2$, M_r 775.67, ϱ 6.14 g/cm^3, forms white hexagonal crystals that decompose at 400 °C. It is insoluble in water, slightly soluble in carbonated water, soluble in nitric acid, and insoluble in ethanol. Basic lead carbonate is made by reacting soluble lead acetate with carbon dioxide in the presence of air. It is no longer used as a white hiding pigment in paints because of its toxicity, but it has many other uses. For example, basic lead carbonate is used as a component of ceramic glazes, as a curing agent with peroxides to form improved polyethylene wire insulation [14], as a color-changing component of temperature-sensitive

inks [15], as a component of lubricating grease [16], and as a component of weighted nylon-reinforced fish nets made of poly(vinyl chloride) fibers [17].

2.3. Lead Halides

Lead combines with the halogens to form the corresponding fluoride, chloride, bromide, and iodide. Some physical properties of the lead halides are listed in Table 2.

Lead fluoride, lead difluoride, PbF_2, is a colorless, orthorhombic crystalline compound up to ca. 220 °C, above which it transforms into the cubic form. Lead fluoride dissolves in nitric acid, but is insoluble in acetone and aqueous ammonia. It is prepared by reacting lead hydroxide or lead carbonate with hydrofluoric acid, or by the reaction of lead nitrate with potassium fluoride. Lead fluoride is used in glass sealing disks for IR sensors [18]; in wear resistant automotive shock absorbers [19]; for the electroless deposition of lead [20]; as a flux for brazing of aluminum and its alloys [21]; in optical glass fibers for IR transmission [22]; and in thin-film batteries [23].

Lead chloride, lead dichloride, $PbCl_2$, forms white orthorhombic needles having refractive indices of 2.199, 2.217, and 2.260. It is slightly soluble in dilute hydrochloric acid and in aqueous ammonia, but is insoluble in ethanol. It is made by reacting lead monoxide or basic lead carbonate with hydrochloric acid, or by treating a solution of lead acetate with hydrochloric acid and allowing the precipitate to settle. Upon heating in air, lead chloride readily forms basic chlorides, for example, $PbCl_2 \cdot Pb(OH)_2$ [*15887-88-4*], which is known as Pattinson's lead white, an artist's pigment. Other uses of lead chloride include: a precursor of organolead compounds [24]; seawater-activated batteries [25]; expanding polymer-based mortar [26]; flux for soldering cast iron and cast brass [27]; sound-insulating rubber sealants [28]; corrosion inhibitor for galvanized steel [29]; and infrared-transmitting glasses for CO_2 lasers [30].

Lead bromide, lead dibromide, $PbBr_2$, forms white orthorhombic crystals that are slightly soluble in aqueous ammonia, soluble in acids and in aqueous potassium bromide (due to complex formation), but insoluble in ethanol. Lead bromide decomposes slowly when exposed to light and darkens due to the formation of lead. It is prepared by reaction of hydrobromic acid with lead monoxide or lead carbonate. Lead bromide is used industrially as a filler for flame-resistant polypropylene [31], in glass optical waveguides for infrared thermometers [32], and for catalysts for producing polyesters [33].

Lead iodide, lead diodide, PbI_2, forms a powder of yellow hexagonal crystals that dissolve in alkalies and in aqueous potassium iodide, but not in ethanol. Lead iodide is made by reacting a water-soluble lead compound with hydroiodic acid or with a soluble metal iodide. It is readily purified by recrystallization from water. Lead iodide is used in aerosols for cloud seeding to produce rain artificially [34]; for making high-contrast photographic images of laser radiation [35]; for high capacity cathodes in lithium batteries [36]; and in low-temperature thermographic copying materials [37].

2.4. Lead Oxides

There are two main oxides of lead, lead monoxide (PbO) and lead dioxide (PbO_2), in which it is divalent and tetravalent, respectively. In addition, lead forms a mixed oxide, Pb_3O_4, and a black oxide which normally contains 60–80 % lead monoxide, the remainder being finely divided metallic lead. The largest market for lead oxides is in the lead–acid battery industry, where lead monoxide is used to prepare the active paste for the electrode grids. The next largest market for lead oxides is the ceramics industry, which employs these compounds for the production of glasses, glazes, and vitreous enamels. Other major markets for lead oxides are the paint and rubber industries.

Another important outlet for lead oxide is for the production of lead salts, particularly those used as heat stabilizers for poly(vinyl chloride) resins, especially basic lead salts. In 1979, the U.S. plastics market consumed ca. 9500 t of lead salts [38]. Because of its electrical and electronic

Table 2. Physical properties of lead halides [8]

properties, lead oxide is used in the production of capacitors, electrophotographic plates, transducers, and ferrimagnetic and ferromagnetic materials. Examples of the latter include mixed oxides, such as lead zirconate – lead titanate, and lead metaniobate.

Some physical properties of the lead oxides are given in Table 3.

Table 3. Physical properties of lead oxides [8]

Compound	CAS registry no.	M_r	Decomp., °C	ϱ, g/cm^3
PbO	[*1317-36-8*]	223.20	1472 (*bp*)	9.53

Pb_2O_3	[*1314-27-8*]	462.40	370	
Pb_3O_4	[*1314-41-6*]	685.60	500	9.1

Lead monoxide, litharge, PbO, exists in a reddish alpha form up to 489 °C; it then transforms to a yellow beta form (massicot), which is stable at high temperatures. It has a water solubility of 17 mg/L at 20 °C, and is soluble in nitric acid, alkalies, lead acetate, ammonium chloride, and chlorides of calcium and strontium. In alkalies, it forms the plumbite ion, PbO_2^{2-}. Lead oxides are produced industrially by thermal processes in which lead is directly oxidized with air. In the ball mill process, metallic lead balls are tumbled in air to produce a "leady" oxide, which typically contains 20 – 35 % free lead. The Barton pot process oxidizes droplets of molten lead at ca. 430 °C to produce either litharge or leady litharge.

The principal use of lead monoxide is in the manufacture of pastes for the grids used in lead – acid batteries. It is also widely used in optical, electrical, and electronic glasses, as well as in glazes for fine tableware. To render the lead compounds insoluble in foods, the glazes and vitreous enamels are prepared from frits, in which the lead monoxide is converted to lead bisilicate, for example. Litharge is also used in rubber as a vulcanizing agent, in lead soaps employed as driers in varnishes, in high-temperature lubricants, as a neutralizing agent in organic syntheses, as a heat stabilizer in plastics, and as a starting material in the production of pigments [40]. The preparation, properties, and other uses of lead oxide are described in [41]. The consumption of litharge in the United States is summarized in Table 4 according to end-use.

Table 4. Litharge consumption in the United States [39]

	Litharge consumption, t			
Industry	1982	1983	1984	1985

Total	*51 677*	*56 540*	*56 898*	*83 933*

Lead dioxide, lead peroxide, plattnerite, PbO_2, is a brownish-black crystalline powder consisting of fine flakes in either the orthorhombic alpha or the tetragonal beta form. Lead dioxide decomposes to lead monoxide when heated above 290 °C. Lead dioxide is practically insoluble in water or alkaline solutions. It dissolves slowly in acetic acid or aqueous ammonium acetate, but more rapidly in hydrochloric acid and in a mixture of nitric acid and hydrogen peroxide. It is produced industrially by the oxidation of red lead (Pb_3O_4) with chlorine in an alkaline slurry. Lead dioxide is electrically conductive and is formed in situ as the active material of the positive plates in lead – acid batteries. Since it is a vigorous oxidizing agent when heated, lead dioxide is used in the manufacture of chemicals, dyes, matches, pyrotechnics, and liquid polysulfide polymers [42]. Other applications of lead

dioxide include antifriction compositions for plastic sliding bearings [43], ballistic modifers in high-energy propellants [44], electrodes for seawater electrolysis [45], filters for desulfurization of waste gases [46], and vulcanizing agents for butyl rubber puncture-sealing layers inside tires [47].

Lead sesquioxide, lead trioxide, Pb_2O_3, is an amorphous, orange-yellow powder. It is insoluble in cold water, it decomposes in hot water, and in acids it decomposes to the corresponding lead salts and lead dioxide. Lead sesquioxide can be prepared from lead dioxide by hydrothermal dissociation. It is used as a ballistic modifier for high-energy propellants [48], as a cathode material in lithium batteries [49], and as an additive to increase the shattering force of explosives [50].

Red lead, lead tetroxide, minium, Pb_3O_4, is a brilliant orange-red pigment. It is insoluble in water and ethanol, but dissolves in acetic acid or hot hydrochloric acid. Red lead is manufactured by heating lead monoxide in a reverberatory furnace in the presence of air at 450 – 500 °C until the desired composition is obtained. It is used as a pigment in anticorrosion paints for steel surfaces and in 1984 accounted for U.S. shipments of 11 236 t [51]. It is also used in lead oxide pastes for tubular lead – acid batteries [52], in ballistic modifiers for high-energy propellants [53], in ceramic glazes for porcelain [54], in lubricants for hot pressing metals [55], in radiation-shielding foam coatings in clinical X-ray exposures [56], and in rubber adhesives for roadway joints [57].

2.5. Lead Silicates

Lead silicates are produced commercially to specific PbO/SiO_2 ratios required by the glass and ceramic, paint, rubber, and plastics industries. Some physical properties of lead silicates are given in Table 5.

Lead monosilicate, lead pyrosilicate, $3\,PbO \cdot 2\,SiO_2$, is a white, trigonal crystalline powder. It is insoluble in water and comprises 85 wt % PbO and 15 wt % SiO_2. Commercial lead monosilicate is produced by dry roasting lead monoxide and silica in the mole ratio 3 : 2. It provides the most economical method of formulating lead-bearing glazes for the ceramics industry and it is also used in the glass industry as a source of PbO.

Lead bisilicate, $PbO \cdot 0.03\,Al_2O_3 \cdot 1.95\,SiO_2$, is a pale yellow powder. It is insoluble in water and has the composition of 65 wt % PbO, 1 wt % Al_2O_3, and 34 wt % SiO_2. It is available in granular form (10 mesh) and as a ground powder (325 mesh). Lead bisilicate was developed as a low-solubility source of lead in ceramic glazes for foodware, for which its low volatility and high viscosity are equally important.

Tribasic lead silicate, $3\,PbO \cdot SiO_2$, is a reddish-yellow powder. It is sparingly soluble in water and has the composition of 92 wt % PbO and 8 wt % SiO_2. It is available in granular form (10 mesh) and as a powder (325 mesh). Tribasic lead silicate has the lowest viscosity of the three commercial lead silicates and it is used primarily by glass and frit producers.

2.6. Lead Sulfates

Lead forms a normal and several basic sulfates. The most important compound is tribasic lead sulfate because of its extensive use in the plastics industry.

Tribasic lead sulfate [*12202-17-4*], $3\,PbO \cdot PbSO_4 \cdot H_2O$, M_r 890.93, ϱ 6.9 g/cm^3, refractive index 2.1, is a fine white powder. Its water solubility is 26.2 mg/L at 18 °C. Tribasic lead sulfate is made by boiling aqueous suspensions of lead oxide and lead sulfate. The anhydrous compound decomposes at 895 °C [59]. The addition of 2 – 7 % tribasic lead sulfate to flexible and rigid poly(vinyl chloride) provides efficient, long-term, economical heat stability. The compound is easily dispersible, has excellent electrical insulation properties, and is an effective activator for azodicarbonamide blowing agents for vinyl foams.

2.7. Other Lead Salts

Several salts of lead are used as heat stabilizers in the processing of poly(vinyl chloride),

Table 5. Physical properties of lead silicates [58]

Compound	CAS registry no.	M_r	*mp*, °C	ϱ, g/cm^3	n_D^{20}
Lead monosilicate	[*10099-76-0*]	294.85	700 – 784	6.50 – 6.65	2.00 – 2.02
Lead bisilicate	[*11120-22-2*]	343.37	788 – 816	4.60 – 4.65	1.72 – 1.74
Tribasic lead silicate	[*12397-06-7*]	729.63	705 – 733	7.52	2.20 – 2.24

alone or in combination with a basic lead salt, such as tribasic lead sulfate. These salts include dibasic lead phthalate [*17976-43-1*]; basic lead sulfate phthalate; and dibasic lead phosphite. In addition, dibasic lead stearate is sometimes employed as a combination internal lubricant and heat stabilizer in poly(vinyl chloride). Lead diamyl dithiocarbamate [*36501-84-5*] has been used as an antioxidant to retard the increase of viscosity and hardness of road asphalts at a loading of 2 – 6 wt % in paving trials in the United States, Canada, and Australia [60]. Further field trials are underway to test the commercial feasibility and environmental acceptability of lead-stabilized paving asphalts.

3. Organolead Compounds

Organolead compounds are those containing one or more lead atoms covalently bonded to at least one carbon atom. Unlike the inorganic compounds of lead, nearly all organolead compounds are derived from tetravalent lead. Table 6 gives examples of organolead compounds in which from one to four carbon atoms are directly attached to a lead atom.

Table 6. Typical organolead compounds [61]

Compound	M_r	*mp*, °C	Uses
$PhPb(OAc)_3$	461.43	102	Polyurethane foam catalyst [62]
$Bu_2Pb(OAc)_2$	439.50	103	Anthelmintic for tapeworms [63]
$Ph_3Pb(OAc)$	497.55	205	Toxicant for shipbottom paints [64]
Et_4Pb	323.45	−137	Anti-knock agent in gasoline [65]

Properties. In general, organolead compounds are well-characterized substances that are quite stable at room temperature. However, they are thermally the least stable of the organometallic compounds of group 14. Most organolead compounds are liable to severe decomposition on heating to 100 – 200 °C, but they are not explosive.

Stable organolead compounds are mostly derived from tetravalent lead and most fall within the four basic categories shown in Table 6, namely, $RPbX_3$, R_2PbX_2, R_3PbX, and R_4Pb (where R is an alkyl or aryl group; and X is a halogen, OH, or an acid radical). The R_2Pb species have limited stability and tend to form R_4Pb upon heating. The tetraorganolead compounds range from the liquid, volatile tetramethyllead [*75-74-1*], $(CH_3)_4Pb$, to the crystalline, nonvolatile tetraaryllead compounds. Some physical properties of tetramethyllead and tetraethyllead are given in Table 7.

Production. The best known industrial process for producing tetramethyllead and tetraethyllead is the reaction of the sodium – lead alloy PbNa with methyl chloride and ethyl chloride, respectively. For example, tetraethyllead [*78-00-2*] is produced according to the reaction:

$$4\,PbNa + 4\,C_2H_5Cl \rightarrow (C_2H_5)_4Pb + 4\,NaCl + 3\,Pb$$

Tetramethyllead (TML) [*75-74-1*] is also manufactured by an electrolytic Grignard reaction:

$$2\,CH_3MgCl + 2\,CH_3Cl + Pb \rightarrow (CH_3)_4Pb + 2\,MgCl_2$$

In a third lead antiknock production process, a chemically redistributed mixture of tetraalkyllead compounds results. Thus, in the presence of selected Lewis acid catalysts (for example, aluminum halides or boron trifluoride), a mixture of TML and TEL undergoes a redistribution reaction in which an equilibrium mixture of the five possible tetraalkyllead compounds is produced.

Economic Aspects. There are three major industrial producers of TEL and lead alkyl antiknock additives for gasoline: Ethyl Corporation, du Pont, and Associated Octel. Data from

Table 7. Physical properties of tetramethyllead and tetraethyllead

Compound	M_r	*mp*, °C	*bp*, °C (kPa)	ϱ, g/cm^3	n_D
Tetramethyllead	267.35	− 27.5	110 (101)	1.995	1.5120
Tetraethyllead	323.45	− 137	91 (2.53)	1.659	1.5195

the International Lead and Zinc Study Group in London indicate a decline of ca. 66 % in the world consumption of refined lead for gasoline additives between 1970 and 1986. Thus, from a peak consumption of 365 200 t in 1970 (excluding Eastern-bloc countries), environmental regulations have resulted in a decline to 124 000 t of refined lead for gasoline additives in 1986 [65]. The limits in 1988 on lead content of gasoline in various countries are given in Table 8. These limits were imposed as a means of meeting automotive emission standards. For catalyst-equipped cars, unleaded gasoline must be used to avoid poisoning of the catalytic converter.

Table 8. Limits on lead content of gasoline in 1988 [66]

Country	Maximum lead in gasoline, g/L
United States	0.026
Canada	0.291
Italy, France, Spain, Portugal	0.399
Other European Community countries	0.151
Australia	0.304 – 0.840
Austria, Sweden, Finland	0.151
Korea	0.301
Venezuela	0.840
Japan	0.000

Uses. Tetraethyllead is used worldwide in gasoline to prevent preignition knock in internal combustion engines prior to completion of the compression stroke. Accordingly, tetraethyllead is commonly called an antiknock agent. This application was for many years the single largest market for organometallic compounds. In addition to providing antiknock qualities to gasolines, organolead additives prevent valve seat wear in engines designed for leaded gasoline.

The preparation and properties of other organolead compounds are described in [67]. Thiomethyl triphenyllead is used as an antifungal agent [68], cotton preservative [69], and lubricant additive [70]; thiopropyl triphenyllead as a rodent repellant [71]; tributyllead acetate as a wood preservative [72] and cotton preservative [73]; tributyllead imidazole as a lubricant additive [74] and cotton preservative [75]; and tributyllead cyanamide and tributyllead cyanoguanidine as lubricant additives [76], [77].

4. Occupational Health

Lead is toxic in all forms, but to different degrees, depending upon the chemical nature and solubility of the lead compound. In general, organolead compounds are more toxic than inorganic lead salts if ingested, inhaled, or absorbed by humans. Children are more sensitive than adults to the effects of lead exposure. Such exposure may be acute (large single dose) or chronic (repeated low doses). Prolonged absorption of lead should be avoided because the toxic effects are many, cumulative, and severe.

The most common indications of the onset of lead poisoning (plumbism) are gastrointestinal, including nausea, diarrhea, anorexia, and constipation followed by colic. Since these symptoms of plumbism may be similar to those of other ailments, blood and urine tests should be made on the basis of prior exposure to lead, clinical symptoms, evidence of increased lead absorption, and significant biochemical changes. Lead absorption can affect hemoglobin synthesis, red blood cell survival time, and neuromuscular function. In addition, the toxic effects of lead in women may include decreased fertility, increased abortion, and neonatal morbidity. Encephalopathy is the most serious result of lead poisoning. It occurs frequently in children, when they have very high blood lead levels, but seldom in adults.

Sources of lead in the environment include soils near smelters, lead-pigmented paints, automobile exhaust emissions, food and water, and industrial exposure. Each of these sources is being reduced or eliminated through environmental and occupational safety regulations. For example, in the United States, the ambient airborne lead limit is 1.5 µg/m^3, measured over

a calendar quarter, which applies to the exterior plant environment and emissions. Moreover, lead-based paints are banned for residential use; leaded gasoline is being phased out; lower limits of lead in drinking water have been proposed (below 20 parts lead per billion parts water).

As a result of exposure monitoring, respiratory protection, protective work clothing and equipment, isolated dining areas, and medical surveillance, there is a very low incidence today of lead poisoning from industrial exposure. Lead-exposed employees in the United States, for example, must be removed from work if the average of their last three blood lead determinations is at or above 50 micrograms lead/100 g whole blood and the airborne lead level is at or above 30 $\mu g/m^3$ [78]. The permissible exposure limit (OSHA-PEL) of lead for industrial workers is 50 $\mu g/m^3$, averaged over an 8-h period. The TLV/TWA for lead is 0.15 mg/m^3, while the MAK value is 0.1 mg/m^3. Tetramethyl- and tetraethyllead have an MAK of 0.05 mg/m^3 (BAT-Wert 50 mg/l) [79].

Abstract

The article contains sections titled:

1. Introduction
2. Economic Significance of Leather
3. Unit Operations of Leather Manufacturing
3.1. The Main Processes
3.2. Chemicals
3.3. Reaction Vessels
3.4. Machines
4. The Raw Material: Hides and Skins
4.1. Production of Hides and Skins, Preservation
4.2. Topographical and Histological Structure and Chemical Composition of Animal Hides
5. Structure and Reactivity of Collagen
5.1. Occurrence and Function of Collagen
5.2. From α-Chains to Fiber Network: The Building Blocks of Collagen
5.3. Role of Water in Collagen
5.4. Biosynthesis of Collagen
6. Processes Preparing the Hides and Skins for Tanning
6.1. Soaking
6.2. Liming, Deliming, Bating, Degreasing
6.2.1. The Use of Enzymes in Leather Processing and in Collagen Upgrading in General
7. Tanning Processes
7.1. General Objectives and Results of Tannage
7.2. Chrome Tannage
7.3. Free-of-Chrome (FOC) Tannage
7.4. Vegetable Tannins and Tannage
7.5. Aromatic Syntans
7.6. Other Tannages including Modern Combination Tannages
8. Processes After Tanning
8.1. Retanning
8.2. Dyeing
8.3. Chemical Lubrication (Fatliquoring), Hydrophobization
8.4. Drying
8.5. Mechanical Softening (Staking, Milling)
9. Leather Finishing
10. Ecological Aspects of Leather Manufacturing
10.1. Ecotoxicology and Occupational Hygiene
10.2. Water and Wastewater
10.3. Solid Byproducts and Wastes
10.4. Air Pollution

11. Leather Properties and Testing
12. Leather Substitutes

[Top of Page]

1. Introduction

Leather is an ancient material and so is the profession of tanner, as shown by old findings of leather and leather goods in different cultures [1]. The tanner is mentioned in very early literature, for example, ARISTOTLE cites SOCRATES: “There are four professions to be the fundamentals of the citation of state: The architect, the weaver, the farmer and the tanner” and the bible mentions “Simon, who was a tanner” [2]. The reason for this importance of leather is clear: Humans needed protection against cold, wetness, and mechanical influences, and hides and skins were available from hunted animals (leather for shoes, garments, gloves, etc.). But leather and leather goods are not only manufactured as a protecting material but also as a fashionable material with aesthetic qualities, e.g., leather for fancy goods, handbags, book binding, and even carpetries, tapetries, etc. [3]. And this double function of leather is still maintained, as the interior of an automobile shows (Fig. 1).

Figure 1. The beauty of leather (example: leather in motor cars)

The many manufacturing processes, types, and properties of leather articles make definition of this material difficult. One possible definition is as follows: “Leather is a material manufactured from the collagen fiber network of hides and skins, endowed with the characteristics required for the intended purpose and produced by suitable chemical and physical processes”.

Thus, collagen is the raw material for the manufacture of leather. After a brief description of the industrial and economical significance of hides, skins, and leather and a survey of the unit operations of leather-making processes, the structure and reactivity of collagen are discussed, as well as the changes to which collagen is subjected during its transformation into leather and how the properties of the latter are influenced by collagen.

[Top of Page]

2. Economic Significance of Leather

Hides and skins, primarily those of cattle, sheep, goats, and pigs, are byproducts of human foodstuffs and wool. Collagen is thus a renewable raw material, the production of which grows in proportion to cattle stock, which in turn is growing in proportion to the earth's human population. The ratio of cattle stock to world human population between 1900 and 2000 remained relatively stable at 0.25 – 0.30.

To get an impression of the economical significance of leather production it is useful to study FAO sources [4], as summarized by BULJAHN [5] and SCHRÖER [6]. World leather production is growing slightly for the reasons mentioned above. Leather production in the developed countries is continuously decreasing, while it is increasing in developing countries, a general trend mainly due to different labor costs. For example, Germany today is an exporter of high-quality cattle hides but only a rather minor leather manufacturer. In contrast, China has recently become a country with a continuously growing leather industry and an major importer of hides, skins, and intermediate products (“wet blue”). Its light leather production rose from 79.5×10^6 m^2 in 1990 to 690.5×10^6 m^2 in 2002. In general, China, India, and Brazil have the elements required for rapid success, and the rest of the world will have to fight for market shares and special niches.

Worldwide, shoe leathers (uppers and linings) are the dominant leather types. World shoe production amounted in 2003 to about 12×10^9 pairs. China alone produces about 7×10^9 pairs, of which 4.2×10^9 pairs are for export. For comparision, Italy, the leading European shoe manufacturer, produces 312×10^6 pairs, of which 297×10^6 are for export [7].

Upholstery leather, especially automotive leather, is winning an increasing market share. In Germany, for example, more than 80 % of all leather types produced are upholstery leather (20×10^6 m^2 in 2001) because of the high quality of the available raw stock (Table 1).

Table 1. The economical importance of the global leather production in developing and developed countries 1990 : 2000 (according to FAO [4])

Type of leather/region	1990	2000	Change 1990 to 2000, %
Light leather, bovine, 10^6 m^2			
Light leather, bovine, 10^6 m^2			
world	872	1027	+18

developing countries	391	619	+57
developed countries	476	413	–13
Light leather, goat/sheep, 10^6 m^2			
world	342	425	+24
developing countries	202	305	+50
developed countries	104	102	–2
Heavy leather, 10^3 t			
world	381	494	+30
developing countries	183	307	+68
developed countries	198	187	–6

An estimated 7 × 10^6 t of hides and skins containing about 2.8 × 10^6 t of collagen are used yearly worldwide for leather production. For technical reasons only 50 % of the hide collagen is converted into leather. Therefore, the utilization of the remaining 50 % of the collagen remains an acute challenge. Some other important collagen-based materials are gelatin, leather boards, casings, medical products, and dog chews (Table 2) [8, 9].

Table 2. Approximate annual production of important collagen-based products (2000)

Collagen-based products	Estimated quantity/proportions
Light leather	1500×10^6 m^2
Bovine	875×10^6 m^2
Sheep/goat	345×10^6 m^2
Pig	250×10^6 m^2
Heavy leather	500×10^3 t
Light leather	100 %
Shoe leather	55 %
Garment leather	20 %
Furniture and automotive leather	15 %
Fancy goods	10 %
Leather board	100×10^3 t
Gelatines/glue	400×10^3 t
Casings (for sausage, etc.)	> 1 × 10^9 running meters of different diametres
Hydrolysates	> 200×10^3 t
Carcass meal (animal feed/fertilizer)	> 2×10^6 t
Collagen in cosmetics, medicine, and tissue engineering (exept gelatin)	3–5×10^3 t

The raw material is the main source of cost in leather manufacturing. The hides and skins account for more than 50 % of leather production costs, and hence leather prices depend on raw-hide prices and their fluctuation. For example, cow and bull hides in France cost, depending on mass class, 1.4 – 1.6 €/kg green weight (October 2004). Assuming an average yield of 0.15 m^2 grain leather/kg rawhide 1 m^2 of grain leather has raw hides costs of about 10 €. Grain leather, the former hair side, is the most valuable part of the hide.

Other important cost elements are chemicals and water, wages, manufacturing and overhead costs, and costs for energy and waste disposal (Fig. 2).

Figure 2. Approximate cost structure of leather manufacturing [10]

[Top of Page]

3. Unit Operations of Leather Manufacturing

Although today leather is a highly sophisticated product and manifold developments of chemicals and machines for leather making took place, mainly in the 1900s [11], the unit operations of leather making remain unchanged. The path from hides and skins of the living animals to finished leather ready for further processing is long and requires many unit operations, very different reaction vessels and machines, manifold chemicals, and a large amount of water.

Useful textbooks on leather manufacturing can be found in [12-18], and a brief introduction to leather manufacturing in [19].

3.1. The Main Processes

Leather manufacturing begins with animal husbandry: The better the hide quality, the better the leather. Two aspects are important here: First, meat is normally more valuable than hides and skins. Second, the hides are at risk of damage by insects and bacterial influences, mechanically caused grazes or flaws, brand marks, and other reasons. Therefore, tanners and farmers are in a permanent discussion of how to improve hide quality and to harmonize their different economical interests.

In the slaughterhouses a careful separation of the hides from the carcasses by flaying is also necessary to ensure high quality. Slaughtering defects like deep cuts, gouges, and even holes should be avoided.

For the time between flaying and processing in the tannery, hides and skins must be protected against microbial attack and putrefaction by preservation. In principle chilling and “instant manufacturing” (short-term preservation), (wet) salting, and drying are the main methods of preservation. The thus-prepared hides and skins arrive at the tanneries in a “green”, “salted”, or “dry” state.

In the tanneries processing begins, often after some storage in well-chilled rooms, with the cleaning of the hides and skins by soaking. It is followed by liming, bating, deliming, all associated with intensive rinsing or with “water-saving” washing. The corium, the leather-forming layer of the hide, must be cleaned from the epidermis along with hairs by liming, and the subcutis (“flesh”) must be removed by defleshing and possibly by degreasing (mainly sheep skins). Often splitting (“in the lime”) of the resulting corium into two or sometimes even three layers (grain and flesh splits) defines the thickness of the future leather, depending on its purpose. This operation takes place in the so-called beamhouse. The name refers to the old tanner's beam, a thick trunk used for manual defleshing a long time ago. The resulting product is called pelt.

It is followed by proper tanning, using inorganic tanning salts and/or natural and synthetic organic tannins. The most important inorganic tannins are basic chromium(III) sulfates. To a much smaller degree basic aluminum sulfates are used. Zirconium, iron, and titanium compounds are only occasionally used as tannins. Among the organic tannins the phenolic vegetable tannins have long been very important. Their substitutes since the 1920s are the so-called aromatic/phenolic syntans. More recent and of growing importance are the polymeric tannins, and also glutaraldehyde and its derivates.

Tanning takes place in the tanyard. In this unit operation the collagen is transformed into the “stabilized” leather matrix, and the pelt is converted to leather. In this state the leather is a wet intermediate product, called “wet blue” in the case of chrome tanned leather, and “wet white” in the case of free-of-chrome (FOC) tanned leather. The names come from the typical color of these intermediate products. The tanned intermediate product is partially mechanically dewatered by sammying (dewatering by feeding through a roller press) and its thickness regulated by shaving (adjustment of thickness by a rotating knife-cylinder). Some tanners split wet blue (“in the blue”) instead of pelts (“in the lime”), but in the latter case there are better possibilities to utilize the collagen waste that is unusable for leather.

During the following wet-end processes the leather is retanned to make the feel of (dry) leather fuller and softer, it is dyestuffed with “aniline” dyestuffs (azo dyestuffs) and chemically lubricated by fatliquoring with different fat emulsions. After washing, the leathers are again mechanically dewatered, and wrinkles and creases are removed by setting out (mechanical dewatering and stretching on a roller machine), often combined with sammying. The leather is then dried and mechanically softened by stretching, called staking, to avoid fibers sticking together. The resulting product is called crust leather.

By finishing the surface of the crust leather with polymer binders and lacquers it is upgraded to the final leather with the grain structure, color, and other desired properties depending on the application. Objectives are protection of the surface, covering defects, and last but not least realization of fashionable effects. The finish layers are thin films of different polymers, containing pigments and some other components, nowadays mainly applied as aqueous dispersions by roll coating and/or spraying (Fig. 3).

Figure 3. The unit operations of leather manufacturing

All the above processes need chemicals, which interact permanently or temporarily with the collagen.

3.2. Chemicals

To convert hide collagen into leather many different chemicals, from simple inorganic salts to highly sophisticated special organic compounds, are necessary. Some of them play only a temporary role but the most important substances — tannins

and fillers, dyestuffs, fats, and filling and finishing polymers — remain in or on the leather.

An impression of the economical significance of the typical “leather chemicals”, including the high water consumption, is given by approximate requirements to produce 1000 m^2 of chrome-tanned shoe upper leather (Table 3).

Table 3. Approximate demand for water and chemicals to produce 1000 m^2 of chrome-tanned grain leather (ca. 7.1 t of wet salted hide) and as byproduct 430 m^2 of split leather from cattle hide [20]

Substance	Quantity, kg (unless otherwise stated)
Water*	215 m^3
Inorganic salts, mainly NaCl*	570
Inorganic and organic acids*	30
Sodium sulfide*	175
Calcium hydroxide*	285
Enzymes*	20
Bactericides*	20
Tensides*	20
Chrome extract (Cr_2O_3)**	700 (175)
Vegetable tannins**	50
Aromatic syntans**	50
Polymers**	50
Resins**	10
Fatliquors**	150
Dyestuffs**	35
Polymer binder (finishing)**	30

*Temporarily applied.
**Permanently fixed on collagen in an amount of 85–98 %.

Relative to the world production of leather (see Table 1) one can see the large quantity and the major economic importance of the most important leather chemicals (Table 4).

Table 4. Quantities of the most important leather chemicals used for world leather production in 2000 (according to [10])

Substance	Quantity, 10^3 t/a (unless otherwise stated)
Water	320×10^6 m^3
Tensides	120
Lime hydrate	300
Sodium sulfide	200
Sodium chloride	270
Chrome extracts (Cr_2O_3)	1600 (400)
Vegetable tannins	300
Aromatic syntans	150
Glutaraldehyde	30
Resins	30
Polymers	150
Lubricating agents	400
Dyestuffs	90
Polymer binder	200

Leather chemicals (performance-type) had a worldwide value of about 3.5×10^9 € in 2002, with the following split between the various leather making processes:

Beamhouse	15 %
Tanning	28 %
Dying	12 %
Finishing	30 %
Commodities	15 %

Table 3 shows also another aspect: The temporarily used chemicals, mainly salts, the incompletely exhausted chemicals, and all the process and wash waters end up in the wastewater [20], cleaning of which in accordance with official regulations is technically demanding and expensive. To improve the processes and the chemicals is a permanent challenge for tanners and suppliers of chemicals (see also Chap. Ecological Aspects of Leather Manufacturing).

3.3. Reaction Vessels

The wet processes of leather manufacturing from the beamhouse up to the wet-end operations take place in different vessels. The interaction between the hides and skins and the chemicals dissolved in the float is a diffusion process and can be accelerated by movement of the hides and the floats. Therefore, the pits that were originally exclusively used are now very seldom found; instead, paddles, especially drums, mixers, and Y-machines ("segmented machines" or "three component vessels" in some variations) are the state of art today (Fig. 4).

Figure 4. Principles of different vessels used in leather manufacturing A) Drum; B) Paddle; C) Mixer

Nowadays, pits are used only occasionally in small tanneries and in special cases of vegetable tanning (ancient pit tannage).

Paddles have long been used. Today they are mainly used for manufacturing light skins. Movement of skins and the float improve the penetration of chemicals into the pelt. Also in fur manufacturing paddles are commonly used.

The invention of drums by the brothers DURIO at the end of the 1800s was a key innovation, that revolutionized the tanning processes. Drums have been the most important vessels ever since. They are advantageous because agitation of the float and the hides or pelts is associated with with tumbling and pumping effects. Both improve the penetration of the chemicals into the hides, pelts, or wet leather. Dry tumbling is done in the crust stage to soften the leather and bring out a fine grain of the leather. This process is called milling.

Drums are normally wooden vessels, but also stainless steel, which is better cleanable and is used especially for dry milling, and even plastic drums are known. They can be very large, up to 40 m^3 in volume. Loading and deloading is highly automated, the floats can be temporarily sampled, and the pH, temperature, and other parameters can be controlled. More recently, highly sophisticated drum constructions have been described [21].

An important alternative to the drum is the mixer or processor ("Challenge Cook"), introduced to tanneries about 1970. It is constructed like a concrete mixer. The advantages and working principles are similar to those of drums.

Y-section vessels (tanning machines, e.g., Dosemat) work almost like a drum but they contain three sections divided by perforated walls. The construction ensures a mild but effective treatment, especially in dying and fatliquoring [22].

3.4. Machines

The conversion of hides and skins to leather is mainly a chemical process with many single steps, but in nearly all stages machines are required. The first important processes are dehairing and defleshing of hides. The regulation of the thickness of the untanned or tanned pelts by splitting in the grain and the flesh splits, possibly with an additional middle split, are further steps.The thickness is is also regulated by shaving in the tanned state.

Another task is the dewatering of pelts or leather in the different states. Beside different kinds of presses, the most important dewatering machines are sammying machines.

The drying of leather is performed by hanging them on dryers in the open air or feeding them through a drying tunnel. The leather can also be fixed under a slight tension on frames and dried (toggling). But the most widely used drying device today is the vacuum dryer, especially for drying shoe upper leather.

Softening the leather is not only a question of fatliquoring but also of mechanical softening by staking and milling.

The finishing of leather needs coating machines; the most frequently used are roll coaters, spraying devices, printing machines, curtain coaters, and padding machinery. Feed embossing presses produce an artificial grain if desired.

In total there are more than 30 different types of machines in a modern tannery. They can be categorised in five groups (Table 5).

Table 5. Mechanical work in leather manufacture and the machinery used therefor (according to [23])

Machine	Function

Multiroller machines	
fleshing machines	removing the subcutis (flesh) from the corium by knife rollers
shaving machines	regulating the thickness of intermediate leather (e.g., wet blue) by knife rollers
sammying machines	mechanical dewatering of tanned hides before shaving
setting machines	mechanical dewatering of wet leather before thermal drying
buffing machines	modification of the leather surface by buffing the grain side (nubuck) or the flesh side (velour)
Splitting machines	
band knife splitting machine	regulating the tickness of hides, pelts, or leather by splitting into two or more layers
Staking machines	
vibration staking types	mechanical softening of the crust leather
arm staking types	
rotary staking types	
Drying machinery	
suspension (hang) dryer	thermal dewatering of wet leather to crust leather
toggle drying machines	
vacuum dryer	
paste dryer	
Secotherm dryer	
Finishing machinery	
padding machines	applying aqueous or organic solutions/dispersions of polymers, pigments, etc. to cover the leather surface, modifying the glance, etc.
spraying machines	
rollcoating machines	
curtain coating machines	
reverse coating machinery	
ironing, plating, embossing, glazing	producing an artificial grain
area measuring machines	measuring leather area

General trends are nowadays the application of the so-called feed-through principle wherever possible and the highly sophisticated use of automation and control, mostly computer-aided. It is not the intention of this chapter to go into details. For details, see [23-25].

[Top of Page]

4. The Raw Material: Hides and Skins

Cattle hides, sheep and goat skins, and to a smaller extent pig skins are the most important raw materials for leather production. The hides and skins of some other animals like horses, crocodiles, birds and fish are used for (special) leather manufacturing.

4.1. Production of Hides and Skins, Preservation

Depending on the average lifetime only a part of the mammalian livestock is annually slaughtered (“slaughtering rate”), and even after slaughtering not all hides and skins are rendered as leather raw material (“flaying quota”). Therefore the relationship between livestock and hide supply is somewhat complicated (Table 6).

Table 6. Livestock, amount of hides and skins (pieces and mass), hides and skins recovery rate in 2000 (according to [4])

Kind/region	Livestock in thousand heads	Hides and skins		Hide recovery rate, %
		10^6 pieces	10^3 t	
Bovine				
world	1 509 492	318.9	576.1*	21

developing countries	665 856	327.5	197.7**	50
developed countries	382 475	198.3	200.6**	51

*Wet salted weight.
**Dry weight.

From the leather-making point of view the hides and skins should be completely intact, and especially the grain layer should be undamaged. Unfortunately, this is rarely the case: Many defects during animal husbandry, cattle transport, slaughtering, and even preservation reduce the value of hides and skins. In general hide quality depends also on the breed, climatic conditions, kind of husbandry, sex, age, etc. Therefore, each hide is individual and all the tanners art is needed to produce a good and constant leather quality.

Instantly after slaughtering/flaying the hides are subject to postmortem changes due to autolytical reactions that are promoted by microbiological attack if not prevented by preservation, that is, the hides and skins must be cured. The oldest method is mild drying of the hides and skins, but this method is not as easy as it seems, as there is a danger of damaging the collagen by drying at too high a temperature or too rapidly. So today drying is rather rarely practiced, mainly in the case of skins.

The classical method of preservation is salting the hides. The dewatering effect of salting hinders bacterial growth. Salt, mainly NaCl, can be applied as solid salt or concentrated salt solutions (brines) in wet salting. The water content of the hides decreases from 70 to < 40 %, and to nearly the same degree salt is incorporated into the hides and must later be removed.

Another kind of preservation with rapidly growing significance is chilling with ice for a certain time during short-term storage and transport to the tanneries. The additional use of bactericides is employed. Sole application of bactericides for short-term curing is used, too, but not so often (Fig. 5).

Figure 5. Fresh hide processing (courtesy of Bader GmbH & Co., Göppingen, Germany)

Some other well-investigated preservation methods use KCl instead NaCl or irradiation with electron or γ beams, but mainly for economic reasons these methods haven't found their way into practical application yet: A radiation device for a large slaughterhouse would cost about 7×10^6 $ [26].

Pickling of skins is state of art in connection with wool production, mainly in New Zealand and Australia.

Finally the instant manufacturing of hides to wet blue in the slaughterhouses or in a plant close by is a very promising future technology.

4.2. Topographical and Histological Structure and Chemical Composition of Animal Hides

The hide's form corresponds to the flaying principle. Concerning leather making the several parts of the hide have different structure of the collagen fiber network and are therefore of different value and specially named (Fig. 6).

Figure 6. The topographical structure of bovine hide (courtesy of Bader GmbH & Co., Göppingen, Germany)

As a rule the central parts (croupons or bends) are of higher quality than the sides: the collagen fiber network there is more compact and denser than in the sides. To compare mechanical properties of leather it is necessary to define the place where the sample is to be taken. During the leather-making process the structural differences can be somewhat lessened, e.g., by selective filling during retanning, but not completely eliminated. Therefore, the specific structure of the hides must be taken into account during the processing of leather.

Hides and skins consist of three main layers: the epidermis, the dermis (corium or cutis), and the hypodermis (subcutis). Each of the layers can be divided into several sublayers (Fig. 7) [27].

Figure 7. The histological structure of bovine hide

The epidermis is a cellular tissue containing the animal hair or the scales of fishes or reptiles. The hair is embedded in the hair follicles. The hair roots are located in the border layer between epidermis and corium. (Only the bristles of pig skins go through the whole corium.) After removing epidermis and hair prior to tannage by chemical dehairing one can see the characteristic grain structure, which is caused by the actual arrangement of the hair depending on the type of animal. The “grain” of the final leather surface is a typical feature of natural leather.

The main protein of hairs and epidermis is keratin. Typical for this protein is the high content of cystine, an amino acid with a disulfide bridge —S —S — which stabilizes the protein structure. When this bridge is destroyed by alkaline, reductive, oxidative, or even enzymatic treatment the hair dissolves or is damaged, so that dehairing is possible. Secondly, the small zone between the grain of corium and the epidermis, the basal membrane, is especially sensitive to the above-mentioned treatments. So it is possible to target this sensitive layer with milder treatments and destroy the hair roots only. The hair shafts remain intact and the hair can be used for certain applications like felt. The removal of hairs and epidermis by the liming process is discussed in Section Liming, Deliming, Bating, Degreasing.

The subcutis (“flesh”) consists mainly of water, fat, and collagen. It is mechanically removed prior to tanning by machine defleshing. The byproduct “fleshings” (glue stock) can be processed to industrial fat, glue, and collagen hydrolysates, but recently the conversion of the collagen hydrolysates and fat to biogas has been of growing importance.

After dehairing and defleshing the pelt remains, built from the relatively thick corium, consisting of two layers, the papillar and the reticular layer. Both layers contain the fibrous network of collagen, mainly of type I, and very small amounts of some other collagens, proteoglycans, elastin, some fat, blood cells, etc., and mainly water (> 70 %).

The papillar layer is less dense than the reticular layer, and the fibers are thinner. The density of the fiber network, the fiber diameter, and the weave angle depend on the topographical position on the hide. A *Histological Atlas* can be found in [28], and leather defects, with many microscopic images, are treated in [29].

[Top of Page]

5. Structure and Reactivity of Collagen

Collagen plays the key role in the leather making process. Therefore, it is necessary to discuss current knowledge of this important protein. Some introductory books and articles from the viewpoint of leather manufacturing are [30-36].

Collagen (from the Greek for glue-forming) is by far the most widely found protein in terms of quantity, and together with cellulose and lignin, one of the three quantitatively dominant biopolymers. This fact is due to its incidence: it is present throughout the entire animal kingdom with the exception of single-celled organisms.

Its significance derives from its function in living organisms. Mammals are a good example: as a component of the mesenchymal connective tissue, collagen is a primary component of the skeleton and the skin, and thus responsible for protecting and supporting the body; it is, however, also present in numerous other organs and, as part of the extracellular matrix, is also of great significance for cellular biology.

Once mocked in biochemical research as “boring” and being of interest at most to leather chemists for their own purposes, collagen now attracts wide attention in many scientific disciplines, and is in fact one of the most closely studied proteins. This can be attributed to the fact that the role played by collagen in cellular processes, in the growth of connective tissue, and also

in the incidence of certain clinical conditions ("collagen diseases") and for the natural ageing of the organism (a human is as old as his or her connective tissue) has increasingly been recognized.

5.1. Occurrence and Function of Collagen

Collagen is now known not to be a single substance, but rather a family of substances. The collagen types now known, 20 or even more by number, differ in some cases considerably in their chemical and structural characteristics, according to their function in the living organism. A common feature is their conformance (at least partially) to a triple helix ("triple-helix domains"), their content of hydroxyproline, an amino acid which is virtually specific to collagen, and their occurrence in the extracellular matrix. Collagens include the fibril-forming types I, II, III (80 – 90 % of all the collagen in the body), V, and XI. Type I is the dominant collagen type of hides and therefore the most important for leather making (Table 7). Other types control fibrils growth and are associated with the fibrils (types IX, XII, XIV), and there are also structures which form networks and filaments (IV, VI). The relationships between the structure of these different collagens and their significance within the living organism is now well documented [37].

Table 7. Data on the structure and reactivity of collagen which are relevant to leather making and wearing

Structural element	Dimensions	Significance for leather characteristics
Amino acids	3 × 1052 amino acids/mol, of which 381 are acidic (Asp, Glu), 268 basic (Arg, Lys, Hyl His), 492 hydroxyl (Hyp, Ser, Thr, Hyl) and ca. 3000 peptide groups	center of reactivity, including water bonding
Molecules	1.4 × 280 nm, ca. 300 000 Dalton	see fibrils
Microfibrils	∅ 40 nm, 5 molecules	metastable intermediate stage in fibril formation
Fibrils	∅ 100–200 nm, intrafibrillar and interfibrillar intervals of up to 20 nm (capillary region) and fibril surface areas of up to 30 m^2/g, depending on water content	location of intrafibrillar activity during conversion of the collagen to the leather matrix (including "cross-linking")
Elementary fibers (fibril strands)	∅ ca. 2 µm	location of interfibrillar activity during conversion of the collagen to the leather matrix (including "coating")
Fibers	∅ ca. 100 µm, intervals in the > 100 nm range (micropores)	largely responsible for garment comfort properties
Fiber network	∅ on the order of mm, woven, intervals in the order of µm (macropores)	largely responsible for mechanical characteristics

5.2. From α-Chains to Fiber Network: The Building Blocks of Collagen

Like keratin, elastin, and silk fibroin, type I collagen is a scleroprotein, consisting like all proteins of amino acids linked by —CONH— groups to form peptide chains. Of the three chains forming collagen, two are identical in the case of type I collagen, α1(I), and one, α2(I), differs in its amino acid composition: $[\alpha 1(I)]_2$ [α2(I)]. The three α-chains which combine to form the triple helix exhibit nonhelical, short-chain appended peptides (telopeptides) at their N- and C-terminal ends. The telopeptides are mobile, do not form helices, and undergo age-dependent cross-linking. They are sensitive to enzymatic attack.

Of the 19 different amino acids involved in the creation of collagen, a third are accounted for by glycine (gly), always in the position gly-xaa-yaa, and almost a further third by the cyclic amino acids proline (pro) and hydroxyproline (hyp). This is a requirement for the collagen-specific formation of a triple helix.

As already mentioned, hydroxyproline (hyp) is virtually specific to collagen, a fact which can be exploited for its quantitative detection. Hyp is also substantially responsible for the hydrothermal stability of native, fully hydrated collagen: the higher the hyp content of a certain type I collagen (e.g., there are significant differences between collagen of fish and mammals) the higher the hydrothermal stability of the collagen triple helices. Fully hydrated collagen in aqueous solution undergoes a helix – coil transition and is denatured at a defined denaturation temperature T_D. If present as a fiber network, as in the case of hide (and leather), denaturation is manifested by shrinkage to a third of the original length of the sample at the shrinkage temperature T_S. Both temperatures are a measure of the hydrothermal stability. The difference between T_D and T_S of mammalian collagen is constant (ca. 25 K).

The content of acidic and basic amino acids, amino acids containing OH groups, and peptide groups is considerable, and is decisive for the reactivity of the collagen, which is a requirement for its transformation into leather. Tanning reactions are discussed in Section General Objectives and Results of Tannage.

The α-chains of the collagen arrange to form higher structures that give rise to a proper structural hierarchy of the collagen. Three α-chains initially combine to form a three-stranded triple helix with a rise of 0.29 nm per amino acid residue and approximately 3.3 amino acid residues per turn. It is mostly assumed that the helix is stabilized by hydrogen bonds, with formation of intrahelical hydrogen bonds by the hyp residues [38]. Recently, an inductive effect of hyp was proposed as the cause of helix stability, and therefore the role of water in helix stabilization needs further discussion [39].

A collagen molecule (“tropocollagen”) soluble in acid and/or citrate buffer is thus formed the dimensions of which (300 × 1.4 nm) can be viewed by TEM or atomic force microscopy (AFM).

Fibrils are assembled from collagen molecules in vivo and in vitro (the process being triggered in the latter case by a change in pH and/or a rise in temperature). The Smith microfibrils constitute a metastable intermediate stage. The microfibrils in this case are successive layers of five molecules forming a “pentagon”. Partial sequences of the Smith microfibril have frequently been the subject of early computer modeling in tanning chemistry.

Since the late 1950s the creation of the fibrils has been well understood owing to the work of KÜHN [40]. Under the influence of their charge pattern, microfibrils are taken up laterally by each other, staggered by a quarter of their length up to an average thickness of 100 nm, and grow longitudinally apparently without limit and with formation of “gaps” between the molecules (see Fig. 10).

The fibrils are accessible to detailed characterization by TEM, SEM, and AFM. The cross-striation pattern typical of collagen with a periodicity of 64 – 67 nm (“D”) was established at an early stage by this means. As the assembly is dependent on the charge pattern, fibril formation can be influenced by modification of the charge pattern. It was thus demonstrated some time ago that transformations on the basic groups involving tungsten triphosphate or on the acidic groups of the collagen involving uranyl compounds cause the typical cross-striation to be highly resolved and more sharply expressed due to the “bringing into register” of the amino acids involved, that is, of their lateral chains - an observation of interest also for tanning chemistry (Fig. 8).

Figure 8. A) A single collagen fibril with significant cross striation (SPM image, courtesy of M. Tuckermann) B) Collagen fibril bundles (SEM image, courtesy of M. Tuckermann)

Using scanning probe microscopy (SPM) with a resolution on the nanometer scale in air and water and by micromanipulation of (tendon) collagen GUTSMANN concluded that the collagen fibril is an inhomogeneous structure composed of a relative hard shell and a softer, less dense core showing a tubelike mechanical behavior [41].

The fibrils continue to grow to form elementary fibers and fibers. The latter then form the fiber network with its great relevance to (mechanical) leather properties. The arrangement of the fibrils can be seen clearly by electron microscopy in cross sections of elementary fibers. The fibrils are bonded to each other not only by cross-linking but also by intertwining.

Finally, the fibers, with a wide range of fiber diameters, ramifications, and reticular networks with the widest conceivable variation in weave angle, grow out of the elementary fibers, as can be seen in a traditional view of a histological section provided by optical microscopy (Fig. 9).

Figure 9. Structural hierarchy of type I collagen in hides

Collagen therefore consists of structural elements which form a structural hierarchy. Up to and including the fibrils, this structure constitutes the microstructure of the collagen, and from the elementary fibers upwards, its macrostructure.

The essential structural data are known and can be exploited for quantitative calculation of material transformations on the collagen, e.g., penetration and binding of tanning materials (Table 7).

The structure of collagen described above is in principle the same for all hide and skin species employed in leather manufacture, in particular as far as the fibrillar microstructure and reactivity are concerned. By contrast, clear differences exist in macrostructure, according to hide and skin species, origin, age, etc. The same applies to noncollagenous constituents such as fat. To these are added topographical differences (“position”) in the hide with regard to weave density and angle of the collagen fibers; these differences also have a decisive bearing on the mechanical properties of the leather. The stratigraphical differences between the individual hide layers, grain membrane, papillary, and reticular layer are considerable.

5.3. Role of Water in Collagen

Water is an integral constituent of the collagen structure. At the molecular level of the collagen structure, the water content acts as nothing else than a “cross-linker” that stabilizes the helix structure to a greater or lesser extent, as discussions between different research groups show [39]. It also stabilizes the intra- and interfibrillar structure; further amounts of water are then responsible for the mobility of fibrils at the interfibrillar level. In other words, water acts both as a “tannin” and a “lubricating agent”. Some types of water are bound on collagen with different firmnesses. Finally, the freely moving intercollagenous bulk water is essential as a solvent for the chemical reactions on the collagen. Reduction or even removal of the different water types has far-reaching consequences (Table 8).

Table 8. The different types of water bound to collagen and their characteristics

Type of water	Amount, g/g collagen	Amount in leather,* %	Type of binding	Strength of binding	Effect when completely removed

H_2O type I (a and b)	a) 0.01 – 0.02	1.1	intra- and interhelical	very strongly bound	helix deformation
	b) 0.02 – 0.07	3.9			
H_2O type II (a, b, and c)	a) 0.07 – 0.3	15	intra- and interfibrillar	from a) to c) decreasingly strongly bound	capillary contraction: volume/area shrinkage; isometric: strain
	b) 0.3 – 0.6	0			
	c) 0.6 – 1.6	0			
H_2O type III	1.6 to > 2.0	0	capillary water ("bulk water")	loosely bound in the fibrous structure or even not bound to collagen	densification of the fiber network, pore contraction, lack of solvent for process chemicals

*Containing 65 % collagen and 15 % water.

Consideration of this "system character" (after BIENKIEWICZ [38]) of leather – water is crucial to an understanding of the tanning process and many properties of collagen and leather. Some important question are, e.g,. what happens to the water shell of collagen fibrils due to the reaction of collagen with tannins? Can tannins act as "lubricating agents" instead of water?

It should suffice here to point out that the thermal stability of collagen and leather is a function of its water content. The thermal stability T_S of water-free collagen is approximately 200 °C and is reduced somewhat by tanning. The hydrothermal stability of fully hydrated skin collagen is known to be only T_S = 60 °C and is increased by vegetable and aldehyde tanning by around 20 K and by chrome tanning by up to 50 K. The glass transition temperature T_G of (dry) collagen and leather lies between 50 °C for native collagen and 70 °C for tanned collagen. It characterizes the transition from the glass- to the rubberlike state, is important for the leather properties, and measured by dynamic mechanical thermo-analysis (DMTA) [42].

5.4. Biosynthesis of Collagen

How is collagen formed? Owing to its significance for cellular processes and the existence of numerous collagens with different functions, the biosynthesis of collagen has been a frequent subject of studies in the domain of cellular biology and biochemistry. A brief summary of the synthesis of type 1 collagen should therefore suffice. The genetic code for collagen is anchored at Position A 64 of the human genome. As the sections of the DNA responsible for collagen synthesis are known and sequence analysis of the nucleic bases is simpler than for the proteins, collagen sequences are in fact now decoded in the main via DNA sequences and stored in suitable databases. Synthesis takes place in the connective tissue cells, the fibroblasts, beginning with the single-stranded α-chains. The latter contain propeptides, both at the N- and the C-terminal ends, which give the strands their solubility. Proline and lysine are not hydroxylated initially. Only in the extracellular space are these propeptides cleaved off, a part of the proline (pro) and lysine (lys) is hydroxylated to hyp and hys, some of the hys residues are glycosylated, and the natural cross-linkages are developed and increase as the connective tissue ages and progressively reduce the solubility of collagen and its ability to swell [43]. Formation of the triple helix requires first cross-linking by disulfide bridges between the mobile telopeptides to ensure the right starting position, zipping the α-chains into a triple helix beginning at the C-terminal end of the chains. These processes are all controlled by enzymes (Fig. 10).

Figure 10. The biosynthesis of type I collagen fibrils (simplified overview)

[Top of Page]

6. Processes Preparing the Hides and Skins for Tanning

Before the actual tannage the hides and skins must be unhaired and defleshed to obtain the corium, the so-called pelt, consisting mainly of water and collagen. Trials have been made on unhairing the whole animal in the slaughterhouse, but for reasons of economics and hygiene, these were not successful till now [44]. Defleshing at the slaughterhouse is practicable but seldom used. So unhairing and defleshing are normally performed in the beamhouse of the tannery. In the case of skins rich of fat, e.g., sheep or pig skin, a chemical and/or in the case of pig skins a mechanical degreasing is necessary [45].

To start this processes a cleaning of the hides and skins is required, the task of soaking. The collagen structure of the pelt must "open up" to ensure the penetration of tannins and other chemicals into its fine structure and to result in soft leathers. This is, besides the dehairing effect, is also the task of liming and bating.

6.1. Soaking

The targets of soaking are manifold: Removal of dirt, dung, blood, and salts, mainly NaCl, in the case of hides preserved by

salting. Also soluble noncollagenous proteins such as albumins and globulins, and proteoglycans must be removed. In all cases complete rehydration of the hide collagen must be ensured. Especially in the case of dried skins it is not so easy to reach this aim. The addition of relatively small amounts of surfactants and proteolytic enzymes (trypsin from pancreas or bacterial proteases) enable shortening of the soaking time. Careful use of enzymes does not attack the collagen [46]. The same is promoted by mechanical movement and therefore the soaking process takes place in drums or very often in mixers. A small addition of bactericides is customary. It is necessary to wash and/or to rinse the soaked hides very intensively, and therefore water consumption is high.

Concerning collagen, soaking is a cleaning and rehydration procedure which will further be developed and completed in the following liming and bating operations.

6.2. Liming, Deliming, Bating, Degreasing

The objectives of these processes are manifold. Liming should achieve dehairing and removal the epidermis and to a certain extent degreasing to give a pure and clean pelt consisting mainly of corium type I collagen and water. This pelt collagen requires “opening up” of the fibril structure to ensure better penetration of tannins and other agents applied later in the leather manufacturing process. The bating process promotes and completes the described effects of liming. Deliming is necessary to remove the liming chemicals, mainly calcium compounds, from the pelt collagen and is normally combined with bating. Intensive washing and rinsing processes are necessary between all these stages.

As mentioned in connection with the histological hide structure, the target of liming is to weaken the basal membrane. An old method is the use of alkali and calcium hydroxide. This has a limited solubility and its saturated solution also a limited pH of around 12. Therefore, too strong swelling or even hydrolysis of collagen can safely be avoided. It is also cheap. Lime alone takes a long time to loosen the epidermis (6 d). Addition of sodium sulfide or sodium hydrogen sulfide drastically accelerates dehairing by reductive cleavage of the cystine bridge of keratin: cystine is reduced to cysteine and the sodium sulfide is oxidized to polysulfide.

Today the standard technology is the application of so-called hair-destroying liming with utilization of relatively large amounts of sulfide. Thus, the keratinous substances are degraded to a slippery mass which can be removed from the grain layer of the pelt by the drum movement alone. This method is quick and complete depilation is ensured. A disadvantage is the high COD load of the wastewater.

In a different technology, a mixture of lime and sulfide is applied to the flesh side only. Hydroxide and sulfide ions diffuse through the hide and arrive at the extremely sensitive basal membrane; thus, hair roots and the epidermis are loosened, but the hair remains completely intact. This so-called “painting” only works with thin skins (goat, sheep, calf) and up to now has been applied ito win undamaged wool (“pulling”).

In another hair-saving process, the keratin of the hair shafts is immunized by mild alkaline teatment. The conversion of cystine to the thioether lanthionine results in high resistance to sulfide, which can attack only the prekeratins at the hair roots. The hair is loosened and can be mechanically separated. Its quality is not so good, but a reduction of the wastewater load is thus achieved.

To avoid the use of sulfide, which can form H_2S under acidic conditions, and the lime load in the wastewater, many alternatives have been developed. A number of organic thio compounds have been used, but for several reasons (e.g., cost, smell) they have not found wider application. In oxidative dehairing with hydrogen peroxide [47, 48], possibly enzyme-aided [49], or sodium perborate [50], cleavage of the —S—S— bridge is caused by oxidation to a sulfonic acid group. However, since this process also has some disadvantages, it has been rather seldom used till now, but there are optimistic opinions about its future chances [51] (Fig. 11).

Figure 11. Cleavage of the cystine bridge of keratin during liming. a) Reductive (e.g., by Na_2S); b) Oxidative (e.g. by H_2O_2); c) Lanthionine formation by alkaline immunization

Especially in the last two decades much work has been done on enzymatic dehairing. Even centuries ago a kind of enzymatic unhairing was applied in the form of the so-called sweating process: the hides were simply hung in a warm room of high humidity. Bacteria rapidly grew and their enzymes loosened the epidermis. This process was very risky and is now not often applied, but the idea of using enzymes survived till now and some progress has been made [52]. However, it is nearly impossible to remove the hair or bristles completely, some hairs always remain in the grain, and so often an additional treatment with sulfide or organic thio compounds is necessary [53].

A more recent example of a substitute for lime is the use of water glass and NaOH [54].

It can be assumed, that the search for ecological better dehairing processes will continue as part of a general strategy of sustainable leather manufacturing [51].

The described operations are performed mostly in drums or mixers, possibly equiped with special appliances for hair recovery, e.g., sieves.

After liming, the hides are defleshed. Although the through-feed multiroller machines themselves are highly automated, defleshing is one of the most physically demanding jobs in the tannery (Fig. 12).

Figure 12. A) Working principle of defleshing machines as an example of multiroller machines in general (see Table 5) a) Hide; b) Knife cylinder B) Defleshing in practice (courtesy of Bader GmbH & Co., Göppingen, Germany)

Splitting machines split the limed hides in two or even more layers. Their operating principle using an endless band knife is used almost exclusively in tanneries (Fig. 13).

Figure 13. A) Working principle of band knife splitting machines a) Unsplitted hide; b) Grain layer; c) Flesh layer; d) Knife (see Table 5); B) Splitting of pelts ("in the green") in practice (courtesy of Bader GmbH & Co., Göppingen, Germany)

The collagen-related "opening up" effect of liming at first involves certain isolation of the collagen fibrils due to mild alkaline swelling [55].The effect is improved by application of certain enzymes to remove noncollagenic components such as proteoglycans [56]. This is an additional argument for using enzymes, even in liming. In the bating process it has long been the state of art. "Opening up" is therefore always a cleaning operation, too [57].

Alkaline liming also always causes a certain degree of desamidation of glutamine and asparagine to the corresponding amino acids with free carboxylic groups. This improves the later reaction of chrome tannins with collagen (see Section Chrome Tannage).

Bating has been an enzymatic process since its invention. Trypsin from pancreas glands has been used since 1908. Later versatile bacterial enzymes, expressed from strains producing enzymes with different optimal pH values, have increasingly been used in bating. They are produced in huge fermenters from bacterial strains genetically engineered for maximal yield. The object of bating is a further cleaning of the grain layer and opening up of the microstructure of collagen [58].

Deliming finally is necessary to remove the Ca^{2+} ions from the pelt. This is done using mild acids like lactic acid, ammonium salts — nowadays rather seldom for ecological reasons (wastewater load) — (di)carboxylic acids, and CO_2.

If degreasing is necessary, as in the case of sheep skin, the application of organic solvents is banned for ecological reasons, as is the use of alkylphenolethoxylates (APE), especially nonylphenolethoxylates. In the course of scientific investigations concerning the role of surface tension during the degreasing process and using computer aided product design a new degreasing agent with special chemical - physical properties and therefore better degreasing effect was developed [59, 60].

6.3. The Use of Enzymes in Leather Processing and in Collagen Upgrading in General

Dog excrement contains bacterial enzymes and was used by tanners for thousands of years for a kind of "bating". Later tryptic proteases were used, and enzymes are gaining growing importance in leather making and collagen utilization in general [61].

The enzymatic removal of dung from hides using mixtures of proteases, amylases, cellulases, hyaluronidase, and others has been intensively investigated [62, 63]. Proteolytic enzymes from different sources are available not only for the beamhouse processes [63], but also for cleaning wet blue [64]. The addition of enzymes to fatliquors is claimed to give softer leather [65]. By using enzymes it is possible to enhance the tanning properties of vegetable tannins by formation of reactive quinones by oxidoreductases in situ or in vitro [66]. Proteolytic enzymes (trypsin or pepsin) are used to hydrolyze leather wastes to recover valuable hydrolysates [67]. The generation of biogas is also an enzymatic process [68].

Transglutaminase (TGA) is used in the food industry as a cross-linker [69] (Fig. 14).

Figure 14. Cross-linking of collagen (proteins) by transglutaminase

TGA can also cross-link collagen hydrolysates and/or gelatins and casein in finishing [70], and the cross-linking of pelt collagen as a kind of tannage has been proposed [71] but also discussed somewhat critically [72]. Cross-linking of casein in

leather finishing by formaldehyde is also possible [73].

Given the above-mentioned developments, further growth of enzyme applications in leather making and collagen upgrading can be foreseen.

[Top of Page]

7. Tanning Processes

Tanning is only one stage in the transformation of collagen into leather, but it remains an important one. For a long time, “tanning” was virtually synonymous with “leather production”, as the tanner and leather maker were one and the same. Vegetable-tanned leathers, which dominated for thousands of years, owed their characteristics to the tanning material due to its presence in high quantities in the leather, for example, in a ratio of almost 1:1 to the hide substance in the case of sole leather. The characteristics of some other heavy vegetable-tanned leathers were determined mainly by the tanning process, too.

The characteristics of glacé leather, a very light and soft leather tanned with alum, salt, egg yolk, and wheat flour were generally regarded as being determined by this tanning process. The same applies to the characteristics of chamois leathers (wash leather), which were simultaneously tanned and softened by fish oils. The decisive role of tanning has also been emphasized for chrome leathers, as chrome tanning endowed the leathers with hitherto unknown characteristics. This form of tannage owed its breakthrough in part to the development of fatliquoring and retannage. In this case the tanning is still important but many other processes are also indispensable (see Chapters Processes After Tanning and Leather Finishing).

What is the current role of tanning in the manufacture of leather? Its first function is now the manufacture of an intermediate which is suitable for partial dehydration and subsequent adjustment of the thickness by shaving and/or splitting. It must be resistent to rapid putrefaction so that it can be stored and transported in the wet state, and can be equipped at a later stage with the desired leather properties in wet finishing. Retannage then completes this primary tanning effect and guarantees, in conjunction with fatliquoring, dyestuffing, and mechanical softening (by staking and milling), the manufacture of serviceable leather. The types of leather most important today, in particular all chrome tanned and free of chrome (FOC) types (generally tanned with glutaraldehyde) are therefore based on a two-stage tanning of this kind. Shoe upper leather, furniture leather, and automotive leather are relevant examples. The division of tanning into two stages simplifies recovery of the byproducts of thickness adjustment of the semifinished products, and allows unconventional pretannages to be used. The recently “rediscovered” sulfur tannage [74] and water glass tannage [54] serve as examples here.

To avoid confusion in the nomenclature the following scheme shown in Figure 15 is used here.

Figure 15. Tanning of light leather with chrome or glutaraldehyde and the like (FOC): a two-step process of pretannage and retannage. Only a combination of both steps truly converts collagen to (crust) leather.

In the following the objectives and results of tanning with respect to the changes in the limed and cleaned collagen are described in a more general way according to Reich [75]. The current theoretical basis of tanning is also briefly treated. Subsequently the most important tannins are explained in detail [76, 77].

7.1. General Objectives and Results of Tannage

Thanks to our knowledge of collagen, it is now possible to define the nature of tanning in the light of the changes brought about on the collagen. Despite all the differences in desired leather characteristics, material structure, and reactivity of the tanning materials employed, the tannages stabilize the collagen structure: tannage prevents the collagen microstructure from collapsing when the water is removed, as is the case when pelts dry to form parchmentlike, hard, and transparent material. This characteristic is accompanied by reduced swelling capacity, enhanced resistance to hydrolytic influences and to microbial and ultimately therefore enzymatic attack, and is often but not necessarily characterized by high hydrothermal stability.

The effects described are permanent in the sense that they do not change significantly even under repeated moistening and drying of the intermediate product thus obtained. A further characteristic is that the tanning materials remain in the leather. Therefore, the following definition of tanning is possible:

Tanning is an industrial process stage during leather manufacture in which the collagen fiber network of the hides and skins is permanently stabilized in its chemistry and structure such that it no longer collapses and adheres to itself when water is withdrawn from it, i.e., it dries out in a leatherlike manner. The intermediate product thus obtained exhibits reduced swelling capacity in the wet condition, is less susceptible to hydrolytic and enzymatic attack, and frequently exhibits also greater hydrothermal stability. All substances which provoke these effects and become part of the leather are tanning materials, irrespective of their chemical structure and the nature of their bond to the collagen.

The changes effected on the collagen by all tanning methods (though to different degrees) are described below in terms of their origin and the methods now available for their demonstration.

Prevention of the collagen structure from collapsing when the water is removed is identical to that what has been described since time immemorial as “leatherlike drying out”. The reason is the retention of air-filled voids between the collagen fibers and fibrils. This characteristic is due to the fact that the collagen fibrils do not adhere to each other during drying. They would be capable of doing so under the influence of the surface tension of the water contributing to their flexibility and the presence of a number of adhesive groups (the meaning of the term “collagen” is, after all, “glue-forming”). They are, however,

prevented from doing so when they are stiffened and/or their reactive groups (those with the potential to adhere/cross-link) are blocked by the tanning materials. This can occur both by cross-linking and by “distance enhancement” and/or mere coating of the surface of the internal structure elements of collagen, all of which involve blocking of the reactive groups (Fig. 16A).

Figure 16. A) Different possibilities of tanning to ensure leatherlike instead of parchmentlike drying out of untanned pelt (schematic); B) The difference between leatherlike and parchmentlike drying out shown by scanning probe (atomic) microscopy (SPM/AFM; courtesy of M. Tuckermann [57])

Conventional microscopic images of dry leather produced by optical, scanning electron or especially scanning probe/atomic force microscopy (SPM/AFM) [78] reveal most impressively the isolation of fibrils and fibers (Fig. 16B).

Leatherlike drying out, which anyone can learn to assess subjectively as soft and warm handle, can also be defined numerically by a number of objective measures. All methods are based on the fact that isolation of the fibers and fibrils and the resulting porosity are measured directly or indirectly by way of the changes in characteristics caused by the porosity, e.g., lower apparent density of leather compared with parchment, and/or are visualized.

Tanning causes a reduced swelling capacity of collagen. Fully hydrated pelt exhibits a water content of over 200% in terms of collagen. The free water, not directly bound to the collagen (bulk water), accounts for the greater part and fills the voids between the collagen fibers and fibrils. The collagen is held together here by covalent cross-linking, electrostatic forces, and hydrogen bonds, which determine the water content and thus the degree of swelling. The natural cross-links increase with the age of the skins [43]: adult collagen thus swells notably less than young collagen. The same applies to the influence of cross-linking tanning: here, too, the degree of swelling and the water content are reduced. This does not become particularly apparent, however, until either the balance between acid and basic groups, which exists at the isoelectric point (IEP) and ensures minimum swelling, is disturbed, or the large number of intracollagenous hydrogen bonds with their stabilizing action is reduced. In both cases, the degree of swelling rises considerably since, due to structural destabilization of the collagen, more space has been created for further uptake of water. The former case applies to acid or alkali swelling; the latter is responsible for hydrotropic, lyotropic swelling. Tanning is capable of reducing both swelling effects.

Tanned collagen has increased hydrolytic resistance. As has already been stated, “collagen” means “glue-forming”, i.e., untanned collagen can be broken down by treatment with hot water and dissolved. This characteristic is eliminated to a greater or lesser degree by tanning, resulting in a complete resistance to hot or even boiling water in the case of chrome leather. The cross-linking action of the tanning materials is responsible for this characteristic. The resistance to dissolution is determined gravimetrically. The result reflects the thermal stability of the tannin – collagen bond. It is lower in the case of hydrogen bond formation than in the case of covalent bonding and highest when both kinds of bonding are combined (see below).

Ever since the effects of tannage were defined, the resistance to putrefaction, that is, the increased resistance to microbial and enzymatic degradation, has been most important. It has seldom been considered, however, that this is a feature of *wet* leather. Leather in this state is however a temporary exception. The improved resistance to microbial (i.e., enzymatic attack) is on the one hand a consequence of the fact that leather, in comparison to hide, contains less soluble substances which could serve as a potential culture medium for microorganisms. On the other hand, cross-linking, as evidenced by the reduced swelling (see above), brings about a delay in the attack, with the effect ultimately of sterically obstructing enzymatic attack. In addition, the tanning materials also act in part as enzyme inhibitors and/or biocides [79].

Owing to the assumed significance of leather's resistance to putrefaction, THOMAS and SEYMOUR-JONES introduced an enzymatic laboratory test as early as 1924. As collagen is resistant to proteases with the exception of collagenases, the rates of degradation of untanned collagen observed with trypsin, pepsin, or papain may be understood only if the test conditions are taken into consideration. These often involve pH or temperature conditions which bring about parallel hydrolytic degradation of the collagen. It is then only logical to conclude that this collagen, already damaged, is also degraded by proteolytic enzymes, i.e., the degradation can at best be delayed by tannage. In other words: resistance to enzyme attack reflects in principle only swelling capacity and hydrolytic resistance. In any case, any person skilled in the art is aware of the susceptibility of (wet) leather (e.g., wet blue) to microbial attack and of the decay of leather in soil.

The increased resistance to microbial attack is a notable characteristic of leather and can be influenced by tanning, but only in the progress of degradation, and not in its ultimate extent. Test methods must be considered critically; tests under practical conditions, geared for example to mold attack on wet blue and its prevention, are of greater relevance. It is regrettable that no reliable data exist for the susceptibility of leather to degradation in standardized composting tests.

The increase in hydrothermal stability, i.e,. the rise in the denaturing temperature of native collagen, has frequently been regarded as *the* characteristic indicating completion of tannage by cross-linking. It is undisputed that the shrinkage temperature T_S, which is based theron, is a quantity of interest in tanning theory. It was first measured by POWARNIN and interpreted in the context of tanning theory as early as 1910. It provides an indication of various types and grades of cross-linking, and its isometric measurement, the principles of which are summarized by TUCKERMANN et al. [80], yields considerable information on the modification which the collagen/leather structure has undergone [81]. Otherwise it provides little indication of the practical value of the leather, as (wet) leather is seldom subjected to thermal load during processing and in use. The thermal load during shaving is also lower than is often assumed. An attainment of as high a T_S value as possible

is therefore also not an objective in the development of new tanning methods, a fact already pointed out very early by GUSTAVSON [82].

Despite this imperative qualification, certain considerations from the perspective of tanning theory are appropriate, particularly since COVINGTON [83-85], RAMASAMI [86], and other scientists in the leather field attempted to formulate a new tanning theory encompassing all tanning processes on the basis of detailed thermodynamic discussions, having in mind the role of water in the collagen – water – tannin matrix, and using new analytical methods like EXAFS [87], computer modeling and model substances as tanning components].

Computer modeling is nowadays of growing importance in leather research, but there are some limitations. Type I collagen itself is too large for modeling as a whole. Therefore, collagen-like polypeptide chains and/or segments of the Smith microfibril with up to 10 – 12 amino acids per chain were used by BROWN et al., who were the first to use computer modeling in leather research [88] and have investigated structural aspects of the N- and C-terminal telopeptides by modeling [89, 90]. The second point concerns the complicated structure of most tannins. Here simplifications are used, as in the case of chrome tannins [91, 92], or model substances, as in the case of phenolic (vegetable) tannins [93, 94]. Fortunately, new paths for synthesis such substances are now available [95]. Up to now not it has not been so easy to perform modeling with consideration of water as integral component of all collagen – tannin reactions. This is mainly due to the required computer capacity and time. Initial attempts were made by FENNEN concerning the chrome – collagen interaction [92] and by SIGGEL and MOLNAR, who investigated the influence of pH changes on collagen swelling. Modeling with 32 triple helices of 46 amino acids per repeated strand in a large “water box” with ca. 215 000 atoms in total is on going at present [96].

Doubtless computer modeling will be an increasingly valuable and necessary tool in fundamental leather research and the product design of tannins.

Possible Interactions on Collagen. The reactivity of the collagen is determined by the functional groups present within it and their accessibility in the various regions of the collagen structure. The bound quantity of collagen is determined primarily by stoichiometric aspects, but is also influenced by available surfaces on the fibrils, elementary fibrils, and fibers, and in the voids between them (capillaries, pores). Another aspect concerns the tannins themselves: They must be able to react with the collagen independent of their special chemical nature in an essentially irreversible fashion (“water-resistant”), and react at least bifunctionally to ensure cross-linking. Their molecular size must also correspond to the distance between the respective reactive groups of the collagen, and their particle size in solution, which is often larger than the molecular size due to aggregation, should allow diffusion through the pores and capillaries (voids) of the collagen into its fine structure, that is, the ability to pass the “diffusion funnel”. This rule is valid for all kinds of penetration of chemicals in leather manufacturing (Fig. 17).

Figure 17. The “diffusion funnel” to be passed by all agents penetrating into the fine structure of collagen

Thanks to current knowledge about the structure and reactivity of collagen and tannins it is possible to summarize the fundamentals of the collagen – tannin interaction (Table 9).

Table 9. The reactivity of collagen with regard to the collagen – tannin interaction

Functionality	Type of bond	Typical tanning materials
Carboxyl groups: COOH	complex bonding	some metal salts, particular basic chromium(III) sulphates
Amino groups: NH_2	covalent bonding	aldehydes, diisocyanates, and other “reactive” (tanning) agents
Ammonium groups: NH_3^+	electrostatic bonding	anionic (tanning) agents, e. g. aromatic syntans
Peptide groups: —CO —NH —	hydrogen bonds	phenolic natural and synthetic tanning materials
Inner surface generally	hydrophobic, and van der Waals bonds	polymers, nonionic tensides and the like with longer alkyl residues, but also all organic tannins to a certain amount
Pores/capillaries	deposited “fillers”	various organic (e.g., some resins) and inorganic agents (e.g., clay, water glasss, sulfur)

The fact that we now know so much about the chemical side of the tannin – collagen interaction is partly due to the fact that a plethora of independent methods exist for demonstrating whether or not interactions have occurred. Their application also permits classification of new or future tanning materials and is a welcome basis for screening.

Despite the high level of our knowledge about tanning theory in general, a lot of questions are still unanswered in detail. When treating the main tannins in the following chapters, some additional remarks will be made in this direction.

7.2. Chrome Tannage

Since the early 1900s chrome tannage has become more and more the dominant tanning process. Today about 85 % of all light leathers are chrome-tanned. The reasons are clear: chrome tannage is a quick, safe, and cheap process, and the wet blue is storable and tradable product which can further be universally processed in many ways to meet special demands for leather properties.

The chrome tannins are nowadays commercially available basic chrome sulfates in which hydroxo (···OH —) and/or ol (—O —) bridges connect polynuclear complexes. The main reactions and terms are shown and explained in Figure 18.

Figure 18. Basification of chrome tannins to form chromium complexes with the aspartic (asp) and/or glutamic acids (glu) of collagen and its cross-linking

In former times tanners produced their own chrome tanning extracts by reduction of chromium(VI) dichromates with thiosulfates, molasses, and/or other reducing chemicals. Today this is done much more effectively by the chemical industry, often using aldehydes as reducing agents. It is also possible to convert Cr^{IV} ions to Cr^{III} ions in situ in the pelt collagen. This was the principle of the first developed and nowadays very seldom applied chrome two-bath tannage.

To avoid a too quick binding of the chromium complexes at the carboxyl groups of collagen they are partially blocked by lowering the pH by the pickle process. The pelt is treated for several hours with dilute sulfuric or formic acid with addition of salt to prevent swelling of collagen. Tanning then begins at lower pH values, later raised by basification, which can be performed with magnesium oxide. Due to the ability of the chromium(III) ion to take up many different ligands into the Cr complex, one can modify the tannin properties ("masking"), e.g., to enhance penetration or to improve chrome exhaustion.

Characteristic of chrome-tanned leather is its high shrinkage temperature; normally it is boilfast (an empirical method to test the success of chrome tanning is comparison of the area of a piece of leather before and after boiling) with T_S > 100 °C.

Only Cr^{III} complexes have tanning properties and only the Cr^{VI} compounds are harmful, even toxic and carcinogenic. Hence, it must be ensured that in the tanning extracts, in the leather, and in the wastes no Cr^{VI} compounds are formed. The absence of Cr^{VI} was taken as absolutely secure knowledge for 100 years, but with the recent increasing accuracy of the analytical methods for leather one could find up to 100 ppm Cr^{VI}. This caused great activities, technological and analytical, to guarantee proper chrome leather quality [97]. Today it can be stated, that in commercial extracts there is no Cr^{VI} and that formation during tanning and wet-end processes can be definitely avoided [98].

In reality this chrome –e collagen interaction (described above) is a simplification. The dominant role of the COOH groups of glutamic and aspartic acids as ligands of bi- or polynuclear chrome complexes is certain [99, 100]. But what is the true nuclearity? What is the specific role of the sulfate ions (there is a distinct different tanning potential between chrome sulfates and chlorides)? What about the other more than 10 complexes of different size and charge detected in chrome tanning solutions, using sophisticated analytical methods [101] and what happens with the "water shell" of collagen (see Section Role of Water in Collagen)?

7.3. Free-of-Chrome (FOC) Tannage

Despite the manifold advantages of chrome tannage FOC tannage is gaining growing importance. One reason for this is that chrome-free solid wastes including worn-out leathers, especially upholstery leathers from automobiles, can be disposed off more easily than chrome tanning wastes, e.g., by incineration. So mainly ecological reasons and a certain pressure by the automobile industry are responsible for the enforced development of FOC leather.

Although there are some different possibilities to produce FOC leathers, the main technology is now a pretannage of the pelt with (modified) glutaraldehyde, mostly in combination with aromatic syntans [102]. After sammying and shaving, the resulting wet whites must be very intensively retanned and fatliquored (see Chap. Processes After Tanning).

Glutaraldehyde has been known as a useful tanning agent since 1960. It is reactive like formaldehyde but at a lower pH, gives sweatproof leather of light yellow color, and reacts very rapidly with collagen. Its vapor pressure is high. Therefore, modified glutaraldehydes, e.g., the acetal produced by reaction with methanol, alkaneglycols, glycerine, saccharides and the like are applied. Such modified glutaraldehydes have some advantages, but the problems with vapor pressure and leather yellowing are not completely solved. To avoid these disadvantages other products are under examination, e.g., reaction products of pyran derivatives with acetone [103].

The reaction between glutaraldehyde and collagen seems clear: cross-linking of the NH_2 groups of two lysine side chains by a covalent reaction with the COH groups of the aldehyde. However, glutaraldehyde reacts very rapidly with itself forming ringlike structures, so the question arises how these react with collagen.

As mentioned, the pretannage must "only" ensure thickness regulation. Recently experiments have been described to achieve this by nearly forgotten technologies using silicates (water glass) [54], sulfur [74], and even iron tannages [104]. Whether these methods will find a broader practical application remains an open question.

7.4. Vegetable Tannins and Tannage

Vegetable tannage is one of the oldest technologies. Many plants, mainly in specific parts like trunk wood, bark, leaves, or

fruits of tropical and subtropical plants contain a sufficient quantity of tannins that commercial exploitation is possible. The tannins are extracted and concentrated to liquid or powdery tannin extracts. They are very often chemically modified by sulfonation for a better solubility or by pH adjustment and the like to ensure better tanning properties [77] (Table 10).

Table 10. Selected information about some important vegetable tannins

Tannin (extract)	Part of plant	Chemical type	Main production region	Remarks
Mimosa (“wattle”)	bark	catechine, condensed	South African states, Brazil	most widely used vegetable tannin, mainly for retanning of light leathers, cultivation in plantations
Quebracho	wood	catechine, condensed	South american states	huge forests, wood winning regulated by “Natural Forestal Laws” also important, especially for tanning heavy leathers
Chestnut	wood	ellagtannin, hydrolyzable	Southern France	large forests, permanent recultivation “allround tannin” for light leather as well as heavy leather
Valonea	acorns	ellagtannin, hydrolyzable	Greece, Turkey	of minor importance, winning in oak forests
Tara	fruits (pods) of *Caesalpina spinosa*	gallotannin, hydrolyzable	Peru	growing importance for FOC leather manufacturing due to its lightfastness but minor amount
Sumach	leaves	gallotannin, hydrolyzable	Italy	of local importance only, gives very bright and lightfast leathers

In practise the tannin extracts of mimosa, quebracho, chestnut, and tara play a dominant role. They are used mainly as retanning and filling material in the wet-end processes in manufacturing of shoe, furniture, automotive, and similar “light” leathers. They are the main tannins in the tannage of sole- and insole leather and similar “heavy” leathers.

All vegetable tannins are pholyphenolic substances [105-107]. That is why they can react with collagen by hydrogen bonding (see Table 9). There are two classes: hydrolyzable and condensed tannins (Fig. 19).

Figure 19. A) Hydrolyzable tannins can be hydrolysed to smaller components, e.g., chebulinic acid to trigalloylglucose and chebulic acid; B) Condensed tannins contain condensation products of smaller units, e.g., dicatechin, the dimer of catechin

As polyphenols these tannins with an molecular weight of about 500 – 800 aggregate in concentrated solutions to colloidal particles with an apparent molecular weight of 10 000 or even more. Such particles can not diffuse into the fine structure of collagen (“diffusion funnel”, see Fig. 17). They remain on its surface and the tanning comes to an end shortly after beginning (“case hardening”). Therefore the “golden rule of tanning” is: Begin with low molecular tannins of small particle size and, when the collagen structure has been stabilized, continue with larger particles. This is a kind of two-step tannage, as mentioned in connection with pretanning.

Concerning the interaction between vegetable tannins and collagen the dominant role of hydrogen bonding is certain, but there are some questions open about the possibility of a partial amount of covalent (quinone) binding: A certain amount of tannin can be extracted from a vegetable-tanned leather without changing the shrinkage temperature T_S. The role of the water shell must be clarified, too. How does water/tannin exchange at the collagen surfaces take place?

7.5. Aromatic Syntans

Originally because of a shortage of vegetable tannins, synthetic tannins or syntans were developed with similar properties to vegetable tannins (exchange tannins/syntans) or with special properties, e.g., the ability to disperse aggregated vegetable tannins or to improve the dying process by shifting charges (auxiliary tannins/syntans) [77]. This basic innovation in 1913 is associated with the name of STIASNY [11].

The basic materials are phenols like phenol itself, naphthol, dihydroxydiphenylsulfone and aromatic substances like naphthalene. These are sulfonated and condensed with formaldehyde, often combined with urea to improve the lightfastness. The order and the extent of these reactions are variable [108]. As a rule, the more phenolic groups and less sulfonic acid groups in the tannin, the better the tanning power (exchange tanning) [109]. The auxiliary tannins are very often condensation products of naphthalenesulfonic acids. Typical exchange tannins are condensation products of unsulfonated

phenols or sulfones and aromatic or phenolic sulfonic acids (Fig. 20).

Figure 20. Approximate constitution of some aromatic syntans. a) A typical naphthalene-based auxiliary tannin; b) Two typical sulfone-based exchange tannins; c) A syntan that is lightfast due to the urea bridges

Depending on their content of phenolic and sulfo groups the reaction of aromatic syntans with collagen is mere hydrogen bonding like vegetable tannins or mostly electrostatic bonding between the NH^+ groups of collagen and the SO_3^- groups of the syntans.

7.6. Other Tannages including Modern Combination Tannages

Well known and also still produced to a small extent is chamois leather. It is made with a very old tannage using oils, especially fish oil with its high content of unsaturated double bonds. The fish oil is stacked into the pelt and oxidized in warm chambers with the result of polymerization and acrolein formulation [110]. After washing out the excess oil by alkaline soda solution, giving a useful fat emulsion (degras), the dried and stacked leather is very soft, alkali resistant, and has a high water-uptake ability. So window cleaning is a well known utilization for chamois leather.

Reactive tannins [108] react covalently with functional groups of collagen, mainly with the ∈-amino groups of lysine. This group includes the quinones, well investigated but without practical significance. More important are the aldehydes. The once used formaldehyde has largely vanished from the tanneries for ecotoxicological reasons [111], but glutaraldehyde plays an important role in the manufacturing of chrome-free (FOC) leathers, as mentioned above [102]. Some other chemicals are potential reactive tannins, for example, oxazolidine, trishydroxypropylphosphine (THP) and carbodiimides, but for economical and/or ecological reasons the play no role in the industrial of leather making.

Combination tannages aim to combine the advantages of one tannin with those of another or to compensate the disadvantage of one by using another type of tanning agent. Nowadays the combination of vegetable tannins with aluminum salts is being reinvestigated. In former times leathers of this type were well known as Dongola leathers but nearly forgotten with the invention of the chrome tannage. Such combinations give a T_S of >100 °C, and the individual tannins applied alone only 75 – 85 °C [112, 113]. A synergistic effect is also found for some other modern combination tannages such are vegetable tannage combined with aldehydes [114], oxazolidines [115], amino resins, and/or THP [116]. They are worth some attention from the practical and theoretical point of view, because they make it possible to produce FOC leather with a high, chrome-leather-like hydrothermal stability of T_S > 100 °C).

Especially in the case of mimosa – oxazolidine tanning the theoretical fundamentals are well investigated [115]. Oxazolidine reacts with the NH_2 group of collagen covalently; the phenolic groups of mimosa are bound at the COOH and/or CONH groups of collagen by hydrogen bonds. Additional oxazolidine cross-links the mimosa tannin. This is also the reason why the T_S is much higher (> 100°C) than that of the leather tanned with the single tannins (Fig. 21).

Figure 21. A) The synergistic effect of combination tannages using vegetable tannins and a tannin with double affinity. a) Collagen cross-linked by oxazolidine only; b) Collagen cross-linked by mimosa tannin and mimosa tannin additionally bound to collagen by oxazolidine [115]; B) The synergistic principle in general: A collagen-bound polyphenolic tannin (mainly mimosa) is additionally bound to collagen and/or cross-linked by an second tannin with double functionality (Al, Cr, and other complex-forming metal ions, aldehydes, oxazolidone, THP, etc. [113])

This is exactly what was postulated by Reich 12 years ago and named the synergistic effect of “substances with double affinity” (“doppelt affine Verbindungen”) [113].

[Top of Page]

8. Processes After Tanning

The tanned leather, partially mechanically dewatered by sammying, thickness-adjusted by shaving and possibly splitting, would become relatively stiff and hard on drying, not like untanned pelt which gives parchment, but too stiff for further processing to leather goods. Especially light leathers need additional retanning to partially fill the voids of the collagen to avoid collapse during drying. This filling should be selective, that is, it should cause an adaptation between the looser structure of the fiber network of the flanks and the denser structure of the butt.

Retanning often effects a remarkable softening of the dried leather, but in most cases an additional softening by fat application is necessary, nowadays mainly in the form of fatliquoring, which was originally developed with chrome tannage 100 years ago.

Dying is mostly performed after retanning and before fatliquoring. All three operations are performed in the same vessels, one after another, with washing and/or rinsing of the leather after the respective operation. Preferably used are the Y-

segmented vessels. Sometimes retannings and fatliquors are simultaneously applied in spray-dried form, using short floats (“compact methods”).

Subsequently the leathers are mechanically dewatered, similarly to the described sammying. But mostly it is combined with stretching to remove wrinkles and creases, the so-called setting out operation. Sammying and setting out are often performed by one machine, known as samm/setting operation.

Finally the leather is dried by very different methods and devices.

Even after the chemical lubrication by fatliquoring leathers need mechanical softening by staking, after-drying, and reconditioning.

Some leathers, mainly certain sport shoe uppers, military leathers, and the like, need hydrophobization to ensure the required watertightness. Also in this field several different technologies exist.

8.1. Retanning

As retanning chemicals vegetable tannins and aromatic syntans are often used. Their filling properties are good, but their equalizing property is poor. They react directly with the collagen and not void-specific; they are “overall” fillers. This is different with resins and polymers, which have no or only little affinity to collagen. They penetrate to where the largest space is, and therefore they are “selective” fillers [77].

Resins are condensation products of urea, melamine, and/or dicyandiamide with formaldehyde [117]. Nowadays they play a more minor role than they did 20 or 30 years ago, but a certain amount is still applied.

Now the polymers are much more important; they are mainly products of the polymerization of (meth)acrylates and/or maleic anhydride, which have long been well known in leather finishing (see Chap. Leather Finishing) and are available as a huge number of different products, and an end of the development is not foreseeable [118, 119]. Modern acrylic polymers act not only as filling tannins but also as lubricating substances, which can partially or completely replace fats. This relatively new product class is called lubricating tanning agents (LTA) [120]. It seems clear that from (meth)acrylate-based polymers further progress can be expected (Fig. 22).

Figure 22. Principal structure of (meth)acrylate- and/or maleic anhydride-based (co)polymers used in retanning, lubrication, and hydrophobization (LTA; according to J.-P. Dix, BASF, Ludwigshafen, Germany)

In general, one can assume that the polymers will gain growing importance and open new paths for a sustainable ecofriendly leather manufacturing. It seems that polymers will be found some day from the beamhouse to the finishing department in all stages of leather production. Patent applications and papers confirm that opinion [121-123].

To choose the right retanning agent in leather manufacturing not only the specific properties, performance, and cost but also ecological aspects must be taken into account [124].

8.2. Dyeing

Leather dying has long been a well-investigated process [125, 126], but newer results are also of theoretical and practical importance [127, 128].

The dyestuffing process is performed mostly using the well known anionic aniline dyestuffs, acid, substantive (direct), 1:2 metal complex dyestuffs, as known from the textile industry (⟶ Azo Dyes – Leather Dyes; ⟶ Metal-Complex Dyes – Leather). Cationic dyestuffs are seldom used; reactives dyestuff do not yet play a role in leather dyestuffing worth mentioning, but this may change in the future [121].

The dyestuffs are available in liquid or powder form, and the desired color recipe can be set up computer aided.

The main dyestuffs in leather dyestuffing are doubtless the classical “Blacks” (Fig. 23).

Figure 23. Typical black dye for leather dying (according to M. Schmitt, BASF, Ludwigshafen, Germany)

The penetration of the dyestuffs and the intensity and levelness of dyestuffing depend on the type of leather, especially on the kind of tannage and/or retannage. For example, in the case of the dominant chrome leather, not only reaction with collagen but also with the collagen-bound chromium complexes must be taken into account. Some ionic additives, e.g., some auxiliary tannins, influence the affinity of dyestuffs by charge modification and thus allow the dyestuffing process to be controlled. The influence of pH is also well known; acidification is used to fix dyestuffs on leather.

8.3. Chemical Lubrication (Fatliquoring), Hydrophobization

Fatliquoring is performed essentially for three reasons. First, the fat contributes to leatherlike, soft drying out of the leather matrix, a function which virtually and by definition lies within the area of tanning. A direct relationship does in fact exist between the type and intensity of tannage on the one hand and the need for fatliquoring on the other. Modern chrome-free tanned automotive leathers are a perfect example of how leather having undergone “meager” tanning can be given the necessary fullness and softness by intense fatliquoring. Second, the water uptake of the leather is reduced, and thus the leather becomes more or less hydrophobic. Third, the application of fat is also important for supplying the leather with sufficient tensile and tear strength. Fatliquoring significantly influences the physical properties of leather in general and these effects of fatliquoring have been manifold investigated [129-131].

Fatliquoring is performed with aqueous emulsions of different natural and/or synthetic oils and fats, made water soluble by well-known reactions [129] (Fig. 24).

Figure 24. Important reactions to produce different raw stocks for fatliquoring (according to J.-P. Dix, BASF AG, Ludwigshafen)

The old-fashioned application of fat by stuffing, used mainly for heavier vegetable-tanned leathers, is nowadays only seldom practiced.

Leather is principally a hydrophilic substrate. Responsible for this is the porous structure of collagen and its hydrophilic groups. For some purposes, e.g., leather for certain sport shoes or military shoes, permanently waterproof leather is needed, and upholstery or garment leather should be hydrophobic, at least water repellent on the surface. In the latter cases easy-care and soil-release properties are desired [132].

There are some possibilities to ensure the described properties. The simplest is spray coating of finished leather with solutions of fluorine and/or silicone-containing polymers, which can protect the surface for a longer time. This procedure can be repeated later by the consumers themselves. The total water uptake is only minimally reduced by such a spray coating, especially when tested under dynamic conditions.

To ensure durable and effective waterproofing other processes are necessary. One possibility is to nearly completely fill the voids and pores with hydrophobic substances such as certain waxes. But in this case the advantage of leather, that is, breathability and ability to adsorb water vapor is lost (“closed hydrophobization”).

A second possibility is fixation of hydrophobic substances at the inner surfaces of the leather. It is advantageous to use substances which can react as ligands towards the bound chrome tannins inside the leather. Stearates are a well-known example. More recently, highly sophisticated polymers have become available. They are mostly acrylate-based products containing COOH functional groups able to bind to chrome complexes and long alkane chains, modified with silicone and/or fluorine derivatives. Often such polymers are said to be amphiphilic. They make the fibrils and fiber surfaces water repellent without closing the voids between (“open hydrophobization”).

It is easier to make waterproof chrome leather than waterproof FOC leather. This is an only partially solved problem and a challenge for the chemical industry [121, 122].

A third possibility of waterproofing is to introduce smaller amounts of water-swellable substances into the voids and pores of leather. Thus, normally the leather remains breathable and of high water vapor adsorption capacity. Only when liquid water penetrates the substances do swelling and pore closure occur, ensuring waterproofing to a certain degree: A hybrid between “open” and “closed” hydrophobization.

8.4. Drying

Drying is one of the key mechanical operations in the leather making process. Leather acquires its final texture, consistency, flexibility, and the drying conditions determine the area gain. Thus, one can find extended chapters on drying in all text books on leather manufacturing; a good overview of the scientific fundamentals of leather drying is given in [133].

The oldest method of leather drying is hang drying at the “open air”. Old tanneries are typically characterized by their high roofs. Hang drying is still applied today. The leathers hang, fixed by clamps, without any tension on belts passing drying channels with regulated temperature and humidity. Sometimes they even pass through the normal workshops (Fig. 25).

Figure 25. Hang drying in a leather factory (courtesy of Bader GmbH & Co., Göppingen, Germany)

It is a mild drying process in which the leather remains relatively soft but it loses a certain amount of area yield, which is an economical problem. Therefore, toggle drying was developed: The leathers are stretched and fixed in that state on wooden

frames by nails or preferably by clamps on wire frames. Depending on the tension before fixation the firmness and stiffness on the one hand and the area yield on the other can be regulated (Fig. 26).

Figure 26. Toggling drying in a leather factory (courtesy of Bader GmbH & Co., Göppingen, Germany)

A newer method is vacuum drying (Fig. 27) [134]. In special devices the leathers are placed with the grain side on heated steel plates and after closing the apparatus vacuum causes rapid dewatering. The advantages are time savings and a finer, smoother grain, but too intensive drying should be avoided, because otherwise the leather will be too hard and stiff, and will show area retention [135, 136]. Therefore, in many tanneries vacuum drying is used as a kind of predrying, completed by a subsequently hang or toggling drying. Not only the drying conditions, but also the “prehistory” of the leather, e.g., kind and intensity of fatliquoring, influence the leather properties after vacuum drying [137].

Figure 27. Vacuum drier “Cartigliano” in a leather factory (taken from *World Leather* 16 (2003) no. 2, 26)

To avoid losing yield and to ensure a fine grain paste drying was developed some decades ago. The leather was spread out on glass plates with the grain side fixed by special aqueous glue pastes, and the plates were introduced into drying tunnels. Another method was Secotherm drying. In this case the leathers were spread onto the outside of metallic hot water tanks. Both methods have the risk of giving hard leather, and they play only a minor role today, if at all.

Having collagen and the leather matrix in mind, it is obvious that drying is a very difficult process: All leathers have a limited hydrothermal stability, the drying temperature must be kept significantly below the shrinkage temperature T_S of the respective leather.

Water transport from the inner surfaces of the leather to the outer surface needs time; too rapid drying would eventually lead to an overdrying of the outside, followed by fiber condensation and thus to blockage of the diffusion process.

As shown in Section Role of Water in Collagen, the bound water is an integral component of the collagen structure. Water types I and II should not be removed by drying, otherwise the collagen structure collapses. That means as a rule that the water content of leather after drying should not be less than 30 % relative to collagen.

Tension during drying brings area gain but also harder leather: The collagen/leather fiber network is stretched as well as densified, so in the practice of leather drying it is necessary to find a reasonable compromise.

8.5. Mechanical Softening (Staking, Milling)

Even a properly tanned, retanned, chemically lubricated, and dried leather tends to be stiff due densification of the fiber network: the fibers are not mobile enough relative to each other. The task of staking, mostly performed after a conditioning of the dryed leather, is to ensure the mobility of the fibers and therefore soft leather handling.

There are different staking machines [23], e.g., the newer vibration or the older arm staking machines which achieve mechanical softening (Fig. 28).

Figure 28. Working principle of a staking machine (modern vibration type)

Again the right water content before staking is very important. If it is too high, the staking seems easier and more effective, but after drying to normal water content during storage the leather will again become hard and stiff. On the other hand, if the leather is too dry before staking the staking effect is insufficient and there is even a risk of damaging the leather grain. Fatliquoring also of influences the staking effect [138].

Milling in drums improves also the softness of the leather and the grain of the leather will be better brought out (mill corn).

[Top of Page]

9. Leather Finishing

The general object of finishing leather is to upgrade the surface of the crusts according to the intended application and especially the grain quality. The leather should look as natural as possible, have the desired color, and should keep its leatherlike warm feel and the other physiological advantages (see Chap. Leather Properties and Testing). The finish should protect the surface against abrasion and other mechanical damages, against spots caused by dirt, water, oil, red wine, and the like [139]. To achieve this target under ecological and economical conditions is a task of the chemical industry [140].

One relatively simple way of upgrading crusts and also split leather is buffing on special buffing machines. The leather fiber network is roughened to fine short single fibers. Buffing the grain side containing the thinner fibers leads to nubuck leather, and buffing the flesh side of grain leather or split leather to suede leather. These velourlike surfaces can be treated by spraying with small quantities of special chemicals to protect the fibers, to improve the layout, and to make the surface water-repellent. This is of course a fine type of leather, but the demand for finished grain leather is much higher and therefore the finishing of leather plays the dominant role.

Finishing grain leather means building a thin layer of natural and/or synthetic polymers, softeners, pigments, dyestuffs, and some other additives on the grain side of the leather.

If the grain is intact and with a natural look, giving the most valuable leather, then only a very thin finish without pigments can be used. Such a leather is called aniline leather. If the grain is slightly defect, the color unequal, and/or the application need special protection of the grain side, a thicker layer is necessary. These layers are pigmented and the leather is called semianiline leather. In both cases the grain is unbuffed. If the grain defects are stronger, the grain side is slightly buffed, followed by a more intensive finishing. Before buffing some grain defects like small holes can be filled with polymer pastes (stucco), a useful and economically interesting upgrading of the grain layer. The result is corrected grain leather.

The difference in intensity of finishing between the above mentioned leather types can be expressed in the number of layers, the quantity applied in grams per square meter, or in the thickness of the finish layers in micrometers (Table 11).

Table 11. The main types of finished leathers and their characteristics

Type of finished leather	Characteristic
Aniline leather	full natural grain, no pigment finish, fully penetrated aniline dying, weight of dry finish layers: 10 – 20 g/m^2, thickness of dry finish layers: ca. 25 µm
Semi-aniline leather	full, light pebbled grain after dry milling, finely dispersed pigments as a light and transparent finish. Possibly slightly buffed grain, lightly pigmented base coat, and transparent top coat, weight of dry finish layers: 20–50 g/m^2, thickness of dry finish layers: ca.100 µm
Corrected grain leather (pigmented finish)	grain slightly or heavily buffed, base coat and top coat often embossed with a grain or fancy pattern, more heavily pigmented, weight of dry finish layers: 50 – 120 g/m^2, thickness of dry finish layers: ca. 150 µm
Heavily finished and/or coated split leather	artificial grain by embossing thick polymer layers, transfer coating or foil application, weight of dry finish layers: ca. 250 g/m^2, thickness of dry finish layers: ca. 0.15 mm
Nubuck leather	grain-side buffed, unfinished, aftertreatment for water and soil repellency, fiber appearance smooth
Suede (velour) leather	flesh-side buffed grain leather or buffed split, fiber appearance rougher

The general structure of the finish, built up by single layers, follows special demands and has its own nomenclature. First there is impregnation of the surface by the so-called impregnation coat. The objective is to guarantee a stable connection between the leather fibers and the polymer layers. These coats are mainly soft, well-penetrating acrylic aqueous polymer dispersions. The leather must be wettable without swelling, and in this context the wet-end processes of leather manufacturing need attention. The next layers are increasingly harder and pigmented, called “base coat”. They are aqueous acrylic and/or butadiene polymer dispersions. Finally the very hard and abrasion resistant top coat is applied. In former times organically dissolved products, e.g., nitrocellulose or polyurethanes, were used. Nowadays the top coats are also aqueous systems, mainly composed of polyurethane, additionally cross-linked to improve hardness and abrasion resistance (Fig. 29).

Figure 29. The principle buildup of leather finish layers

As mentioned above the main film-building polymers (“polymeric binders”) are polyacrylates, polybutadienes, and polyurethanes [141]. Polyacrylate dispersions [118] used in leather finishing since about 1935. The polyurethanes [142] started as (organically dissolved) finishing products ca. 1940 in the field of patent leather production and today also have a large share of (aqueous) binders. In the case of aniline leather casein is also used. Nitrocellulose plays a rather marginal role today. Both binders need an external plasticizer, e.g. modified castor oil, phosphate esters etc.

The polymers are to an increasing extent aqueous dispersions, but organic solvents are applied in some cases to ensure special properties. The polymers are synthesized in such a way that an external plasticizer is not necessary ("internal plasticization"). The dispersions are often foamed to reduce water consumption and to ensure thin layers using thickener and therefore safer application.

To ensure proper abrasion resistance, heat stability, and the like most polymer binders need cross-linking. Types of cross-linker include carbodiimides, isocyanates, and modified polyaziridines.

The finish systems are applied mainly by roll coater (base coat) and preferably by spraying (top coat; Fig. 30).

Figure 30. A modern finish unit (spray device "Spraystar" of Gemata S.p.A., Trissino (VI), Italy) in a leather factory (taken from World Leather **16** (2003) no 7, 46)

Other coating methods are available: printing, curtain coating, transfer finishing using release paper, and the like [23]. Between the application of the single layers very often embossing or ironing takes place to improve the connection between the polymers and the leather (impregnation) and between the polymer layers themselves.

Newer developments concern, for example, the application of high-solids systems such as reactive polyurethanes and/or polyacrylate polyurethanes, hardening by UV radiation, and powder coating. [140].

[Top of Page]

10. Ecological Aspects of Leather Manufacturing

Leather manufacturing was not environmentally friendly in the old days. Processing a biological substrate like hides and skins with dog excrement as enzyme source produced a terrible smell and therefore in ancient times the tanners were banished to live outside the village. Today a modern tannery is more ecofriendly, but major efforts are necessary to attain this.

Strict regulations have made intensive endeavours, expensive investment in water treatment, and flexibility necessary to survive as tannery. Indeed many tanneries in Europe and elsewhere closed in the last few decades. Earlier the regulations and laws in some developing countries were not so strict as in the developed countries, but nowadays such differences are more and more eliminated and it is coming to a worldwide harmonized level of ecological demands.

Therefore, "sustainable" leather manufacturing is needed, and in this connection the chemical industry plays an very important role. Very impressive examples for new thinking are given in [143]. For example, it is possible to produce a dry polymer-based FOC intermediate instead of the traditional wet white (LUPA process). Its low water content and weight is economically very advantageous and the best protection against putrefaction. It can be transported and stored without any restriction. It can be quickly and completely resoaked, which is impossible in the case of dryed wet blue (see Section Chrome Tannage) and processed to FOC or chrome leather. The shavings are free of chrome; their utilization causes no problems.

10.1. Ecotoxicology and Occupational Hygiene

Toxic substances are no longer applied in leather making: carcinogenic amines have been banished from dyestuffs and PCP from preservation, the Cr^{VI} risk can be avoided, and formaldehyde is nearly banished, too. The same is with NMP (*N*-methyl-2-pyrrolidon), in former times a component of polyurethane synthesis [144]. NPE (nonylphenol ethoxylate) APE (alkylphenol ethoxylate) have also largely vanished. The technological conditions exclude risks which are theoretical conceivable, e.g., erroneous acidification of sodium sulfide containing floats with release of hydrogen sulfide. There is a very useful document available called "clean leather technology" [145]. Working in a tannery today is a hard job as before, esepcially in the beamhouse, but not a dangerous profession.

10.2. Water and Wastewater

Leather manufacturing needs a lot of water to perform the wet (float) processes and the manifold washing operations. Not only the water consumption but also the cleaning of the wastewater causes high costs. For many years now tanners have therefore paid attention to minimizing water consumption. The success is shown by the following figures: Water consumption to manufacture 1t of bovine hides was more than 200 m^3 in 1950, about 150 m^3 in 1975, and less than 25 m^3 in 2000 (average values for tanneries with high technical level). Washing instead of rinsing, low float processes, and water/float recycling were some ways to reach this aim.

Besides the quantitative aspect the qualitative composition of the wastewater is most important. The wastewater of tanneries, with its high load of inorganic salts and organic matter of chemically very different kinds, sludge, and sediments, requires complicated measures (Table 12).

Table 12. Approximate composition of a typical wastewater (according to [20])

Quantity	Quantity of effluent load/1000 m^2 grain leather and, as byproduct, 430 m^2 split leather, causing 215 m^3 effluent	
	Load in mg/L	Total amount in kg

Suspended solids (SS)	116	25
Chemical oxygen demand (COD)	188	40
Biological oxygen demand (BOD_5)	68	15
Cr^{3+}	5	1
S^{2-}	7	1.5
Ammonium nitrogen (NH_3-N)	5	1
Total Kjeldahl nitrogen (TKN)	15	3
Cl^-	170	36
SO_4^{2-}	81	17

As in other industries, everything has been done to avoid or to minimize wastes. Salt-free preserving, substitution of ammonium salts in deliming, pickle-free chrome tanning, highly exhaustive chrome tannage, chrome recycling, and the like are well known steps in the right direction.

Cleaning the unavoidably highly loaded wastewater needs the combined application of mechanical, chemical, and biological efforts (Fig. 31).

Figure 31. Simplified flow scheme of wastewater cleaning

Membrane processes are gaining in importance in wastewater treatment in the different operations of leather making [146], especially for desalination [147]. Membrane processes are also widely applied for the removal of salts, monomers etc. from syntans, dyestuffs, and the like [124].

Figure 32 shows a modern wastewater treatment plant of a large tannery.

Figure 32. A modern device of tannery wastewater cleaning (courtesy of VDL, Frankfurt/Main, Germany)

10.3. Solid Byproducts and Wastes

As mentioned above only ca. 50 % of the collagen is transformed into leather. The remaining 50 % is found in different solid wastes, for example, the trimmings and fleshings, unusable tanned or untanned splits and shavings, buffing dust, and so on [148]. There are some possibilities of utilization (Table 13), e.g., shavings can be manufactured into leather boards [149] or, after dechroming, converted by very different processes [36] to collagen hydrolysates and reusable chrome tannin. However, large quantities remain unused. Burning leather wastes has recently been a much discussed point, but the Cr^{VI} content of ashes when burning chrome leather must be considered.

Table 13. The main solid byproducts and/or wastes of manufacturing 1000 m^2 of grain leather and their practical and proposed utilization (partially according to [20])

Type of solid waste	Quantity/1000 m^2 "light leather", kg	Realised and/or proposed utilization
Fleshings/trimmings	2840	fat, hydrolysate, biogas, increasing burning
Splits from pelt or tanned intermediates, for leather usable	530 (pelt split), 370 (Cr split)	leather (suede, artificial grain)
Splits from pelt, for leather unusable	655	gelatin, casings, hydrolysates,
Splits from tanned intermediates, for leather unusable	525 (only in the case of splitting in the chrome)	see shavings

Shavings, chrome-tanned	700	hydrolysis: protein and Cr^{III} recovery, leather board
Shavings, FOC-tanned	700	fertilizer
Finished leather cuttings	210	biogas, burning

10.4. Air Pollution

Beside the normal and harmless typical smell of a tannery, the critical air pollution inside and outside the tanneries comes from the finish department, especially from the spraying machines (spray dust). Fortunately, the problem is eased by highly effective absorbers and by the fact that more and more aqueous systems are used for finishing. Buffing dust is filtered out and therefore no longer a danger.

A certain risk lies in the application of aldehydes, but the possibilities to avoid harmful effects have been mentioned above.

Some accidents happened occasionally due to H_2S, but only when a major mistake was made (acidification of beamhouse floats). In the USA since 1971 some 32 people died in such accidents.

Concerning the traditional chrome and FOC leather production there are no principle ecological advantages of the one or the other kind of tannage, except some special chromium aspects as mentioned above. That is not so surprising: The most critical process steps are beamhouse and wet-end operations [150, 151]. A very useful survey of environmental aspects of leather manufacturing is given in [152].

[Top of Page]

11. Leather Properties and Testing

The performance of leather has its origin in the physical and chemical structure of collagen, modified by the leather making process. The structure – properties relationship is thus comparatively well known [153].

Which of the manifold properties of leather are particularly important depends on its intended purpose. For example, for automotive leather there are more than 20 relevant parameters, tested in part by specially developed test methods. Therefore, this modern leather type is in a true sense a “high-tech leather”. Especially in the case of automotive leather, the very different climatic conditions which cars are exposed to worldwide must be taken into account, from arctic to tropical temperature, humidity, and sunshine (UV radiation) intensities. Leather should be heatfast, lightfast, nonshrinking, and the like, independent of these different environmental conditions. Another example is the fogging risk. When leather releases volatile substances (VOC) under the influence of heat then these substances can condense on the windscreen of the car and fog it. Nowadays only fogging-free leather has a chance to be used in cars, test methods are carefully developed, and the threshold for acceptable fogging values is very low [154].

More generally speaking and having collagen in mind, leather properties can be divided into three different categories: aesthetic, physiological, and physical/mechanical.

The esthetic properties comprise the appearance of leather, which should be as natural as possible, that means with a non “polymer-covered”, natural grain or a suede surface of nubuck or velour type. Leather should have a good warm handle, soft feel, and the smell should be leatherlike. It is possible to incorporate perfume-filled nanoparticles into the leather [155].

The physiological properties ensure the wearing comfort of leather goods which are in direct contact with the body: shoes, gloves, garments, and upholstery. Very important in this context is the permeability to water vapor (“breathability”) and especially the ability of leather to take up to about 30 % of its weight in water from the water vapor in the surrounding near-body near atmosphere without feeling wet (“water vapor adsorption ability”). Both properties are uniquely realized in leather and are due to the porous structure of collagen and its hydrophilic groups.

The good insulating behavior against heat and cold is also a welcome characteristic of leather and is also due to its porosity. Naturally, a porous and hydrophilic substrate cannot be waterproof. This would be a disadvantage for the utilization of leather in some cases. Fortunately, there are modern methods of leather impregnation that ensure a high degree of waterproofness without impairing the breathability and the ability to adsorb water vapor (see Section Chemical Lubrication (Fatliquoring), Hydrophobization).

The physical/mechanical properties of leather ensure its durability, resistance to mechanical influences, and thus guarantee a protective function. A very important property of leather is its unique stress – strain behavior. Weak forces easily cause a reversible tension of the leather to a certain point (netlike deformation, Fig. 33), then the resistance against more tension increases dramatically (elastic deformation). These properties are very important for ensuring wearing comfort, e.g., of shoes and gloves. It is a unique advantage of leather that these properties can be influenced by the technical conditions during the leather making process.

Figure 33. The unique stress – behavior of leather: “netlike” deformation of the leather fiber network at low stress, important for wear comfort of shoes and gloves [156].

Test methods for leather are standardized, partially at a national level (e.g., DIN in Germany), at an international level (e.g., EU standards), and/or by the scientific societies of leather chemists. The International Union of Leather Technologists and

Chemists Society (IULTCS) has long been very active in this field since. International commissions of experts are permanently developing and updating test methods for physical (IUP), chemical (IUC), and fastness (IUF) properties. There are almost 100 such methods, often identical with the ISO standards. An overview of leather testing is given in [157].

In the future new test methods will be developed, whereby growing importance will be attached to nondestructive test methods, e.g., based on acoustic emission [158].

Beside the test methods agreements about the tolerable data are necessary. They depend on the special purpose of the leather and have to be agreed upon between the leather manufacturer and the leather processor.

12. Leather Substitutes

See also ⟶

Since ancient times other materials have been used beside leather used for the same purpose, e.g., textiles for shoes and garments. Leather was preferred where it had the better properties for the specific article and/or where it is the more valuable material to meet the highest demands. Leather substitution must take into account both aspects. At the beginning of the machine age leather belts for power transmission dominated. Later rubber-coated textile belts came on the market, cheaper and of similar suitability. A real progress from the engineering point of view was brought by the V-belt and more recently by the direct drive. The result is that leather belts today are found only in technical museums. The same happened with other technical leathers once used, e.g., as so-called “textile leathers” in textile machinery.

An other example is sole leather. Apart from wooden soles of special shoes, leather was from the beginning of shoe making the only sole material used. This changed dramatically during the industrial and chemical revolution in the 1800s and 1900s century. Rubber soles showed a longer life than leather soles, and the different polymer-based soles (PP, PUR etc.) were foamed and therefore lighter. From the point of high productivity of industrial shoe manufacturing the direct molding of soles to shoe uppers was a further motive to substitute leather. But even today many elegant shoes are supplied with a leather sole.

The most important reason to develop leather substitutes was to meet the growing demand of materials for garments, upholstery, shoes, etc. Without substitutes it would be quite impossible to safeguard a high level of supply with all the necessary things for daily life. Thus, at the end of the 1800s the time of artificial leather had come. Nowadays the production of the different kinds of artificial leather is more than twice that of leather and, as a rule, there is no strong competition between both materials but a “peaceful coexistence” [159].

From the beginning the target for developing artificial leather was to achieve the optical and haptic properties of leather. Till now the construction principle has remained nearly unchanged: a textile base is coated with a special natural or synthetic polymer and its surface is then subjected to leatherlike finishing, as described in Chapter Leather Finishing (Fig. 34).

Figure 34. The principle structure of artificial leather

The different kinds of textile bases include fabrics, tricots, and impregnated nonwovens, based on natural and/or synthetic fibers, even microfibers. The polymer layer was originally made with linseed oil, later with organically dissolved nitrocellulose, and then mainly using PVC paste, mostly foamed in different ways, and finally by using organic- or water-based or high-solids (“reactive”) polyurethane. The coating can take place directly, using a doctor knife or (reverse) roll coating, or by transfer coating using release paper or endless steel bands (Sandwick principle). The finishing is similar to leather finishing, but printing dominates; also spraying is practiced. Embossing is possible by machines or, in the case of transfer finish, the structure is given by the (negative) grain structure of the transfer paper (Table 14).

Table 14. Artificial leather: main types, worldwide production, prices

Type of artificial leather	Approximate annual production world wide, 10^6 m^2	Average price, €/m^2
PVC compact artificial leather	1000	1
PVC foamed artificial leather	1500	2
PUR compact artificial leather	500	3
PUR microporous artificial leather, nonwoven base	30	8
PUR microporous artificial leather, fabric/tricot base	150	6
PUR microporous artificial leather without base	5	6
PUR impregnated microfiber artificial leather	40	25

Total	3220	
In comparison: leather	1700	40

Three more recent basic innovations should be mentioned here: The first concerns the production of porous, “breathable” polyurethane layers by the coagulation technique, the so-called “poromerics” (Corfam, Clarino, etc). The special PUR is dissolved in dimethylformamide and the substrate coated. Then the material is introduced into a water vapor saturated channel (precoagulation) and then passed through water baths in a countercurrent principle. The DMF is washed out, and the PUR loses its solubility and precipitates, building a microporous structure. The coagulation technique has been further modified in different ways [160].

The second innovation is the production of microfibers with a very fine titer (high yarn count), similar to collagen fibers in diameter. They are produced by the so-called matrix technology: a mixture of fiber-forming (e.g., polyester or polyamide) and matrix (e.g., polystyrene) polymer components is extruded to an endless fiber. After extraction by organic solvent (e.g., toluene) of the matrix the fibers are split off as microfibers with a diameter not achievable by direct spin extrusion. These fibers are processed to a nonwoven and impregnated by coagulation technology with a very leatherlike aspect. Its surface is of nubuck type (Alcantara) and can be finished similar to leather (Lorica). Products of this kind have been on the market for about 20 years now; they have the most leatherlike look and are also breathable. However, their adsorption capacity for water vapor is only about 10 % of that of leather.

Finally, a class of materials which are not a really artificial leather but is often combined with leather, are the so-called membrane composites. They are waterproof but permeable to water vapor. Combined with textiles in sports wear such membranes ensure comfort by waterproofness and breathability. Such membranes can also be found in sport shoes. A prominent example is Goretex, a PTFE-based film microporized by stretching. Other possibilities to achieve this aim are the incorporation of hydrophilic segments in PUR foil (Helsapor) or the application of a special coagulation technique.

In conclusion it can be said that artificial leather is no threat for leather; on the contrary, it is a welcome addition to meet the demand. Moreover, “real leather” has, beside its manifold advantages, the image of a unique and valuable material, manufactured from a renewable biomaterial. So the slogan is still right: “Leather, an old material with a bright future”!

1. Definition and History

Leather imitates (leatherlike materials) are flexible sheets that have a surface structure similar to that of leather. They are usually composed of a polymeric coating and a carrier layer. Coated leather imitates with a textile carrier can be divided into three categories depending on the type of textile used: woven fabrics, knits, or nonwovens. Film leather imitates are compact or foamed plastic films with a leatherlike surface [7].

From the mid-1700s, leather imitates were produced in England and in Germany by coating textiles with air-drying boiled linseed oils. The slow-drying boiled oils were replaced by nitrocellulose coatings at the beginning of the twentieth century. These leather imitates were used for the interior décor of cars [8]. It was not until about 1935 that poly(vinyl chloride) (PVC) was introduced as a coating material; it is still used as a pasty mixture of PVC powder and a liquid plasticizer, which is spread on a textile carrier and hardened by heating. Foaming agents have been used since the 1950s to produce thick, soft coatings that have permitted the use of leather imitates in new areas. Even today, most leather imitates are coated with PVC.

Polyurethanes and other polymers for coating were introduced around 1960. Polyurethane products were mainly produced by using solvent-based coating systems with the coagulation method (see Section 4.2.2). Increasing demands on product properties resulted in the development of solvent-deficient, end-capped, high-solids polyurethane systems in the late 1970s [9], which can be applied by transfer coating.

In future, development will be controled by technical performance demands and environmental aspects and will lead to tailor-made products for each specific application. These factors already played an important role in the development of reactive high-solids polyurethane systems [10], [11] and thermoplastic polyolefins (TPO) as base materials for leather imitates.

2. Properties

A leather imitate, irrespective of its application, should have the appearance and feel of leather. This includes the grain, a dry feel, and a certain degree of softness. Chemical and physical properties are not uniform; they are determined by the structure and nature of the materials used, and depend on the intended application of the leather imitate. Important properties are resistance to abrasion, cleansing agents, common chemicals, light, and heat, as well as a certain extensibility. The type of carrier material selected is determined by the mechanical demands made on the leather imitate; depending on the application, it must also be rotproof, insensitive to moisture, or heat resistant. Leather imitates must be sewn, glued, welded, and thermally shaped during processing. Imitates used for apparel and footwear must simulate the wearing quality of leather; they should be permeable to water vapor and be

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_283

able to absorb moisture; their flexibility is often better than that of leather.

Leather consists of collagen fibrils that become increasingly compressed in the direction of the surface (→ Leather, Chap. 2.). Grained leather imitates, however, are usually multilayered (Fig. 1) and consist of at least one carrier material and one covering layer. The carrier is usually a textile or a plastic film which gives the leather imitate a certain firmness. To meet the specific demands, different constructions may be chosen.

Figure 1. Construction of leather imitates
a) Lacquer; b) Dense top coat; c) Intermediate layer; d) Laminating adhesive; e) Textile carrier

Optical appearance, as well as the feel and touch of the composite, are defined by the transparent lacquer used as finish. By using different additives, these properties are adjusted to specific applications. Formulations with good resistance to light, scratching, and abrasion are used as top coats, since the physical, chemical, and mechanical properties of the surface are determined by this layer. Soft imitation leather contains a layer of foam below the covering layer, but this intermediate layer may also be dense. To avoid impression of the textile structure from the carrier at the surface, foamed constructions are used. By using suitable laminating adhesives, a strong compound of coating and carrier is achieved.

3. Raw Materials

A carrier-free foam, i.e., a *film leather imitate*, is made up of a covering layer and a foam layer. *Thin compact imitation leather* consists solely of a polymer film with a leatherlike grain.

Suede imitates are either composed of several layers, the covering layer being napped or provided with short fibers (Benella), or consist of a uniform nonwoven fabric of bundled microfibers (Alcantara or Lorica) [12]. Microfiber nonwovens simulate the appearance and feel of leather and have very similar wearing qualities.

Leather fiber materials consist of finely ground leather fibers and a binding agent; the leather fibers may also be mixed with textile or cellulose fibers.

3.1. Carrier Materials

The mechanical properties of a leather imitate, such as extensibility, tear resistance, and tear propagation, are mainly determined by the carrier. Woven fabrics, knits, or nonwovens can be used as carrier depending on the demands made on the finished product. These textiles consist of yarn or fibers made of cotton, other cellulose materials, polyamide, polyester, polypropylene, or mixtures of these substances. The yarn can be preshrunk or textured.

Woven fabrics are usually coated by the direct coating method (see Section 4.2.2) to produce leather imitates that are tear resistant and not very extensible. The types of weave commonly used are linen, twill, and satin; weights vary from 100 to 500 g/m^2. The cut edges of leather imitates made from woven fabrics tend to fray. The coating material penetrates into the fabric and the resistance to tear propagation of the leather imitate is poorer than that of the uncoated fabric. Fabric leather imitates are employed, for example, in cabriolet roofs.

Knits are used as carrier when softness and extensibility are required of the imitation leather. Warp or weft knits can be made in different ways; tricot and interlock knits are commonly used. Weights vary from 60 to 300 g/m^2. Undesirable penetration of the coating material into the knit can be avoided by using the transfer coating technique (see Section 4.2.2). Knitted carriers are very extensible because they consist of coiled threads; they are less elastic in the longitudinal direction than in the transverse direction. Projecting edges of the carrier easily roll into the coating mass during coating; this can be prevented by using knits with glued edges. Knitted leather imitates find wide application in upholstery and car seats.

Nonwovens. Many different leather imitates can be produced from nonwovens because of the large number of ways of combining fibers, fiber laying, and fixing methods (→ Nonwoven Fabrics). These products have leatherlike mechanical properties, such as low resiliency on extension. The binder content of splitting felt on a weight basis can be up to three times the fiber content; coating is performed by the direct method. Since needle-punch nonwovens with up to approximately 20 wt % binder readily absorb the coating material during direct coating, they are produced by the transfer coating technique. In the coating of nonwovens with PVC, attention must be paid to interaction between the binder and the coating, e.g., migration of plasticizer from the coating into the binder used in the nonwoven.

Microfiber nonwovens are now being used as new textile base materials for high-class leather imitates. Microfibers are fibers with a maximum linear density of 1 dtex; ultrafine or ultrasuperfine microfibers have values of around 0.09 – 0.13 dtex [13]. Since such fine fibers can not be spun and processed, special conjugated fibers and islands-in-a-sea fibers (i.e., the microfibers are extruded in removable, soluble matrix) with finenesses of greater than 1 dtex are used. After processing they are split into ultrafine fibers by treatment with solvents, alkali, or high-pressure water jets. The majority of conjugate fibers splittable by hydro-de-entanglement are produced in the Far East as staple fibers for processing on carding machines. Finishing (e.g., coagulation) and coloring leads to microfiber nonwovens with mechanical, optical, and feel and touch properties comparable to those of leather.

The weights of nonwovens used for coating lie between 30 and 600 g/m^2. The leather imitates are mainly used in the shoe industry.

Other carriers. Films made of acrylonitrile – butadiene – styrene copolymer (ABS), unplasticized PVC, polyethylene, and polypropylene are used mainly for the interior décor of cars. Similar to fabric carriers, films can also be covered with a coating or provided with a leather grain and possibly a foam layer on the reverse side. Small amounts of cardboard, paper, mats, and netting are also coated for certain applications.

3.2. Coating Materials

Poly(Vinyl Chloride). The coating material most often used for leather imitates is a plasticized (flexible) poly(vinyl chloride) [*9002-89-5*] [→ Poly(Vinyl Chloride)]. A thick viscous paste is produced by mixing 100 parts of PVC powder with 30 to 120 parts of a liquid plasticizer. This vinyl plastisol consists of a stable dispersion of PVC in the plasticizer. It is first coated onto the carrier and then fused by heating and gives a thermoplastic material. During this process, the plasticizer migrates into the swelling PVC particles, and most of the particle boundaries disappear. The plasticizer in plasticized PVC is relatively mobile because it is only bound by physical interactions. It can exude to the surface of the leather imitate as a sticky film, especially after heating, or it can be extracted from the coating by fats and plastics, such as polystyrene or certain polyurethanes. The plasticizers are generally esters of phthalic acid, aliphatic dicarboxylic acids, or fatty acids [14]. They influence the processing conditions and the properties of the final product. The migration tendency and the volatility of the plasticizer decrease with increasing length and branching of the hydrocarbon chain derived from the alcohol. However, the viscosity of the paste and the fusing temperature simultaneously increase, and the PVC paste becomes less workable. Straight-chain esters improve the low-temperature flexibility of the coating. Polymer plasticizers (oligoesters) have a very low migration tendency. To give the coating the desired properties, several plasticizers are often combined.

The amount of phthalate plasticizers emitted by evaporation from soft PVC products into interiors is relatively low (< 0.1 %) [15]. Larger amounts may be extracted by direct contact with materials which are miscible with the plasticizer (e.g., polyether-based polyurethane foams). In risk assessments for phthalate plasticizers, no toxicological, mutagenic, or environmental effects have been found [16–18]. Nevertheless, public discussion led to the development of so-called green PVC products containing nonaromatic plastisizers (e.g., esters of citric acid [19]).

The addition of metallic soaps, epoxides, organic phosphites, or organic sulfur – tin compounds confers stability to light and heat on plasticized PVC. Cadmium and lead salts have

now been largely replaced by barium, calcium, or zinc compounds for environmental reasons. Other additives are pigments, fillers (e.g., $CaCO_3$), flameproofing agents, and, if necessary, foaming agents, lubricants, and biocides.

The production of leather imitates with PVC pastes is economical and relatively simple. Coated surfaces can be heat-embossed with various grains. In the course of further processing, the products can be subjected to high-frequency, ultrasonic, or thermal welding and can also be glued. The leather imitates are mechanically insensitive, stable to alcohol, acids, and bases and, with suitable stabilization, very weatherproof.

Disadvantages of PVC coatings are the strong dependency of the modulus of elasticity on temperature and plasticizer mobility. The leather imitates must be lacquered to make sure that they feel dry and leatherlike. They can become brittle as a result of plasticizer migration.

Polyurethanes are the second most important class of coating materials. They do not require a plasticizer, and even small amounts produce tenacious, abrasion-resistant surfaces. Leather imitates constructed with polyurethane are mostly used for high-quality products. Polyurethanes for coating are made from aromatic or aliphatic diisocyanates. The polyol components also determine the polyurethane quality and are predominantly polyesters; polycarbonates are, however, sometimes employed (→ Polyurethanes).

One-component systems consist of solvent-based linear polyurethanes (solids content 20–30 %) or aqueous dispersions [20] (solids content 20–40 %). After spreading, film formation is carried out by evaporating the organic solvent or water in a drying tunnel. Polyurethane solutions used in the coagulation method (see page 9) contain a water-miscible solvent, frequently DMF. Addition of slow-reacting polyfunctional cross-linkers (e.g., aliphatic polyisocyanates) leads to coatings with increased stability against solvents or cleaning agents. Due to their low solids content one-component polyurethane systems are used for the preparation of thin films (20–100 μm) such as lacquers, top coats, and laminating adhesives [21].

Solvent-deficient, high-solids or solvent-free prepolymer systems are being increasingly employed for environmental reasons. The addition of a hardening agent, usually an isocyanate, causes cross-linking of the coating on drying and the loss of thermoplastic properties. The reactive groups of the hardener are often reversibly blocked in the process and can be thermally activated. Hence, the shelf-life of the coating material is controllable, and coatings derived from aqueous dispersions can be cross-linked above 100 °C after evaporation of the water. In the coating process the isocyanate groups are reformed by removal of the protecting group [e.g., 2-butanone oxime (**1**)] at elevated temperatures (Fig. 2) [22], [9].

The isocyanate end group then reacts with the chain extender (e.g., the cycloaliphatic diamine **2**). This leads to an increase in molecular mass and formation of the polyurethane film. By using cycloaliphatic diamines as chain extenders, poly(urea urethanes) with excellent physical and chemical properties are formed. The rate-determing deblocking reaction ($k_1 \ll k_2$) can not be catalyzed. Therefore, the rate of formation can only be increased by using higher temperatures. Residues of the protecting group remain in the product and result in high values in TVOC (total volatile organic compounds) measurements and a characteristic smell of the final product.

High-solid polyurethane formulations which are stable at room temperature without using reversible protection of the isocyanate groups have been developed in the mid 1970s [10], [11]. Handling is more demanding since contaminants (e.g., traces of water) strongly influence the pot life and reactivity of these systems. Coatings based on these raw materials contain very small amounts of volatile organic compounds, as is demanded for various applications. High-solid polyurethane systems are used to produce thick layers (0.2–0.6 mm) such as the intermediate coating.

Stabilizers [e.g., phenolic antioxidants or hindered amine light stabilizers (HALS)] increase the thermal and light stability of polyurethane coatings. Other additives are pigments, fillers, and flame-proofing and foaming agents.

Polyurethanes have the major advantage that they yield flexible, exceptionally tenacious, solvent-resistant coatings without a plasticizer. They are, however, sensitive to strong acids and bases. When polyurethanes are employed as coating materials, the raw materials used

Figure 2. Chain extension of polyurethane prepolymers protected by 2-butanone oxime (**1**)

for their synthesis must be selected to comply with the requirements demanded of the coatings. Polyurethanes from aromatic diisocyanates are light-resistant and less expensive but display poor lightfastness. The more expensive aliphatic diisocyanates yield polyurethanes with a higher lightfastness. If the polyol component is a polyester, the polyurethane may be sensitive to hydrolysis. Its mechanical stability deteriorates under the influence of humidity and heat. Polycarbonates yield polyurethanes that are more resistant to hydrolysis. Modern polyurethane formulations combine good hydrolytic stablility with lightfastness, light and thermal resistance.

Other Raw Materials. Other Raw Materials. Ethylene – vinyl acetate copolymers and butadiene copolymers are also processed in solution or as dispersions. Polyamide coatings usually contain a plasticizer and are produced from alcoholic solutions. They are insufficiently stable to water and alcohol to be used in most applications. Unplasticized PVC, ABS, and thermoplastic polyolefins (TPO) can be employed for hot-melt coating or are first converted into films and then laminated on a carrier (e.g., sponge leather). TPO-based decorative foils are predominantly made by thermal lamination of extruded films on compact films or polyolefin foams as carrier. The TPO leather imitates are derived from textile carriers (e.g., nonwovens). To meet the technical demands on TPO foils, blends of a thermoplastic polyolefin matrix (e.g., polypropylene) and reinforcing elastomeric rubber components (e.g., EPDM) are used as raw materials.

3.3. Lacquers for Finishing

The surface of leather imitates, especially those made of plasticized PVC or TPO, must be lacquered to give them the feel of leather. Pigmented lacquers can be used to produce a leatherlike design; matt varnishes give the desired finish and dry feel. The lacquer also protects the surface: it improves the slip, acts as a plasticizer barrier, and reduces abrasion and soiling. Resistance to light and heat can also be increased.

The finishing lacquers are generally solutions of polyacrylate and PVC in organic solvents.

The lacquer film may be 3 – 20 µm thick. Plasticized PVC coatings can be lacquered with brittle acrylates because the lacquer film absorbs plasticizer from the PVC layer and becomes more flexible. Acrylate lacquers are very resistant to light and temperature, but cold forming of the leather imitate can cause whitening due to cracking and partial peeling of the lacquer film.

Polyurethane lacquers are generally applied as two-component systems. Depending on the degree of cross-linking of the polyurethane, the lacquer film either remains flexible or becomes hard, scratch-proof, and solvent resistant. The resistance of polyurethane lacquers to light and temperature is not as high as that of polyacrylate lacquers. Lacquers based on polyamide are stable to plasticizers, but are not sufficiently resistant to alcohol and water.

The solids content of solvent-containing lacquers usually does not exceed 15 %. Large amounts of highly volatile solvents are liberated on drying; contamination of the atmosphere should be prevented. Part of the organic solvent penetrates into the coating during lacquer application; this interferes with further processing and results in higher amounts of volatile organic compounds (VOC) in the end product. For these reasons, efforts have been made to develop aqueous lacquers for leather imitates. Appropriate dispersions consist of polyurethane or polyurethane – polyacrylate mixtures along with low amounts (< 10 %) of high boiling cosolvents (e.g., *N*-methylpyrrolidone). In new product developments, normally only aqueous lacquer systems are considered.

4. Production

4.1. Layer Composition

A thin primer layer is often applied to synthetic fabric carriers. Carriers can be bound to the coating with the help of a laminating coat of, for example, plasticized PVC. The overlying layers can vary in material, density, plasticizer content, stabilization, and filler content. When coating with plasticized PVC, a surface layer containing less plasticizer and more filler gives a dry, resistant surface. The underlying layer then contains more plasticizer to improve strength at low temperatures. A base layer of plasticized PVC can also be combined with a thin covering layer of a suitable polyurethane for the same reason.

Foamed leather imitates are produced in large quantities and contain a foam layer between the covering layer and the carrier. This foam layer may be 0.2 to 3 mm thick depending on the application; it is produced either as whipped foam before application to the carrier or by adding a chemical blowing agent which reacts during gelling of the coating (→ Foamed Plastics, Chap. 2.).

Foamed leather imitates without a carrier are mainly made of plasticized PVC and are produced in similar quantities to foamed leather imitates with a textile carrier. Special mechanical properties are not required because the films are subsequently laminated onto solid carriers.

Film leather imitates from calendered films are made up of one or more layers. In multilayer imitates, two or three thin films are laminated using heat and pressure to give a single film. The product can be embossed at the same time with a leatherlike grain. Films are often glued on the reverse side and are consequently provided with an adhesive primer. The application of a foam layer made of plasticized PVC, polyurethane or, less often, of polyethylene or polypropylene on the reverse side confers a certain softness to the film leather imitate.

4.2. Coating

Knife coating is the traditional and still most important method of coating. The coating material must be liquid or pasty. It is applied to the carrier and the carrier is then pulled under a knife or doctor blade which is placed at right angles to the direction of travel. The coating is subsequently hardened under heating radiators or in a drying tunnel.

An important processing parameter of the liquid coating materials is their viscosity. Most coating machines require viscous pastes to prevent the coating from flowing off the carrier during application or from penetrating too deep into the textile carrier. Therefore, solutions and thin dispersions are thickened with an appropriate agent. The paste is subjected to high shearing forces during application, and the viscosity should not increase too strongly as a result of

the dilatant flow behavior of the paste at a high shearing rate gradient [23].

Poly(vinyl chloride) pastes are made in a mixer by stirring the PVC powder and the solid additives into the liquid plasticizer. Reduced pressure facilitates the wetting of the PVC particles. Pigment additives must be distributed very uniformly; consequently, it is useful to disperse them in a plasticizer and mill them in a roll mill before addition to the paste. The pastes should be deaerated before application by stirring under vacuum to avoid air bubbles in the coat.

4.2.1. Coating Devices

The paste is applied with either a doctor (knife) or a roll. Different types of *doctor knives* can be employed (Fig. 3). Pointed doctor knives are used for coatings that are not penetrable and for small quantities. Doctors with wide profiles can be employed to produce coatings that are several millimeters thick. The wide nose with a sharp edge is designed to prevent formation of drops that fall into the wet coating and produce defects; such defects often occur in pastes exhibiting dilatant flow. The type of doctor coater chosen depends on the quantity of coating applied and on the type of carrier used.

Figure 3. Types of doctor blade

In the case of floating knife coaters (Fig. 4A, B) and blanket coaters (Fig. 4C, D), the carrier is pressed firmly against the knife; this is required for the application of thin base coats on fabrics. A knife-over-roll coater (Fig. 4E), in which the space between doctor blade and carrier can be precisely adjusted, is used for the application of thicker layers up to ca. 1 mm.

The use of *applicator rolls* is of advantage for coating weights of 10 – 100 g/m^2. The coating material is transferred onto the carrier by the applicator roll, which is wetted with the paste. In direct roll coating, the applicator roll takes the paste out of a coating pan (Fig. 5A). The reverse roll coater is based on the indirect method (Fig. 5B). A metering roller removes surplus paste from the applicator roll which rotates counter to the direction of travel of the carrier. Other processes use a screen cylinder (Fig. 6A), a gravure roll (Fig. 6B), or other roller systems [24], [25].

Figure 4. Knife coating systems

4.2.2. Coating Processes

Coating may be performed by either the direct or the transfer method.

Direct Coating. Direct application of the coating material to the carrier is suitable for woven fabrics, films, and, to a limited extent, for nonwovens. The carrier for the leather imitate is placed on a reeling off device (Fig. 7a) and then passed through the coating stations (b, d). A predryer (c) is positioned behind each coating station and may consist of a short drying tunnel,

Figure 5. Direct roll coating (A) and indirect (reverse roll) coating (B)

IR radiators, or heated rollers. After predrying, known as pregelling in the case of plasticized PVC, the coating is hard enough to take another layer. In general, two to three coats may be applied. The coating attains its final firmness in a long main drying tunnel (e) in which a foam may also be produced if the layer already contains a chemical blowing agent. In this gas- or steam-heated tunnel, hot air of up to approximately 200 °C flows at right angles to the web (i.e., vertically). A guiding tenter can be used to avoid shrinking of the product in the tunnel. After passing through the main tunnel, the coated carrier is cooled (e.g., on water-filled rollers, f) and then wound in lengths of 100 – 1000 m on large reels.

The fabric used for direct coating must be dense and free of knots. It is usually washed and desized before processing. In the first coating station a thin base coat is applied in the form of a highly viscous paste. The paste should not pass through the carrier nor penetrate too deeply into it because this would result in a deterioration of the mechanical properties of the carrier. Pastes for foam and covering layers are applied in the following coating stations. The smooth surface of the coated material is lacquered (see Section 3.3) and embossed with a leatherlike grain in subsequent production steps.

Transfer Coating. In the transfer or reverse coating method, the coating material is spread as a paste on a release paper (Fig. 8a). As in direct coating, several coating stations with pregelling units can be used. The carrier for the leather imitate is placed on a reeling-off device and is applied to the coating after the last wet-coating step. Alternatively, an adhesive paste may be printed onto the pregelled coating. The textile or film carrier is then laminated to this layer. The reusable release paper is removed from the hardened coating after it has passed through the main drying tunnel. These release papers may be impregnated with silicone and must have a certain adhesiveness for the coating. The coating must not slip in the drying tunnel or on the rollers, but must also be easily detachable.

The reverse technique has many advantages over the direct method. The carrier for the leather imitate is stressed very little during production, so that light fabrics and, above all, knits can be used. The release papers can be provided with

a negative profile of the leather grain. A leather imitate with the desired heat-stable grain is then obtained. Carrier-free foam films can only be produced by the reverse method. A disadvantage of this method is the additional paper cost.

Other Coating Methods. Thermoplastic polymers are also processed by using extrusion coating or the melt roll coating process [26].

In the *extrusion coating process,* a thin layer of the coating material is extruded through a slot die directly onto the carrier (Fig. 9). This method requires polymers with a narrow softening range such as low-density polyethylene. The *melt roll coating process* is suitable for a series of thermoplasts (e.g., PVC, polypropylene, polyethylene, and polystyrene) which are formed into a film on a calender and subsequently heat-laminated to the carrier on the last calender roll (Fig. 10). For the production of compact film leather imitates, single films are usually formed on a calender which are then thermally laminated in doubling and tripling machines and simultaneously provided with a leatherlike grain. The grained films can subsequently be coated with a foam layer or laminated with a foam sheet. This method produces leather imitates that are similar to the foam films made by the reverse coating technique.

Porous, vapor-permeable coatings (poromerics) can be made by the *coagulation method* (Fig. 11). The coating material, usually a polyurethane, is dissolved in a water-miscible solvent (e.g., dimethylformamide) and spread on a textile carrier. The coating hardens as the solvent is gradually displaced by water. The water-insoluble coating coagulates to give a porous film. This method is used, for example, to produce a moisture-storing base layer which can be covered with a compact covering layer by the reverse method. Leather imitates of this type are used in the shoe industry.

4.2.3. Finishing

Most leather imitates are printed and lacquered (see Section 3.3) to improve the finished surface of the material. The pigmented lacquers and transparent varnishes are usually applied by gravure printing. Other printing processes are also used, such as letterpress, flexography, or screen printing. The finish can be adjusted by using dull lacquers.

Embossing. Smooth thermoplastic coatings obtain their leatherlike grain in a final step by hot embossing (Fig. 12). The grain is usually pressed

into the softened surface with a roll. Before embossing the coating is heated to 120 – 220 °C, with heating rolls (a) and IR radiators (b), and is then pressed onto the engraved steel embossing roll (c) with a rubber roll (d). Cooling of the embossing roll improves the heat stability of the grain. However, the grain collapses if the leather imitate is heated to approximately the embossing temperature during further processing.

In the embossing of foamed layers, a gap must be set between the embossing roll and the rubber roll to avoid destruction of the foam layer.

Figure 12. Embossing calender
a) Heating roll; b) IR radiator; c) Embossing roll; d) Backing roll; e) Cooling rolls

Embossing devices can be integrated in the coating plant. Embossing can be carried out immediately after coating especially in the case of foamless layers applied on a calender.

A natural leather grain can be reproduced almost perfectly on an embossing roll, which can be used to produce leather imitates with a very leatherlike surface.

Suede imitates are produced by various methods. After the coating process the covering layer can be roughened by sanding or flocked with short synthetic fibers (e.g., polyamide fibers). In addition, the covering layer can acquire a surface of short fibers made from the coating material (e.g., polyurethane) during the coating procedure.

Suede imitates based on nonwovens can be made from microfibers, which are bundled and encased in a polymer (e.g., polystyrene). After production the nonwoven fabric is hardened with coagulated polyurethane. The covering polymer is subsequently removed by dissolution, leaving the microfibers with a certain mobility and increasing the surface area of the impregnated nonwoven fabric.

5. Quality Specifications and Analysis

Varying demands are made on leather imitates depending on the intended application of the product. It is not possible to meet all these requirements at the same time. A large number of test methods have been developed to determine the physical and chemical properties. These methods are documented, e.g., in ASTM, DIN, and ISO specifications. Certain properties of leather imitates are important in all applications and are generally tested according to standard methods. These include measurements of the tear resistance and the tear propagation strength. Furthermore, it is important to determine the adherence between carrier and coating, the extensibility, and abrasion resistance. Aging resistance is tested by storing the leather imitate at very high or very low temperature in the presence of light or in the dark before mechanical testing. Polyurethane leather imitates, in particular, are subjected to damp, warm storage (hydrolysis test).

The *automobile industry* is an important purchaser of leather imitates and has developed its own quality criteria and tests [27]. This application requires especially heat-resistant, lightfast leather imitates, which do not embrittle in the cold and are abrasion resistant. Moreover, they must frequently have a flame retarding finish. Since the volatile components of leather imitates can cloud the windows (fogging effect); low-fogging leather imitates produced from low-fogging raw materials are being increasingly used.

The *shoe industry* has taken over many test methods (ASTM, DIN, ISO) from the leather field. Apart from the mechanical strength, abrasion resistance and cold flex temperature are of importance. In addition, the permeability to water vapor and the water storage capacity should be measured. Leather imitates used in *apparel applications* must be perspiration-resistant and fast to washing or dry cleaning.

6. Economic Aspects and Uses

The total production of leather imitates can only be estimated. In 2000 the production of textile and film leather imitates in Western Europe, with the exception of Spain, Portugal, and the Scandinavian countries, was approximately $500 \times 10^6 \mathrm{m}^2$. The automobile industry was the largest consumer with approximately $275 \times 10^6\,\mathrm{m}^2$(film leather imitates ca. $135 \times 10^6\,\mathrm{m}^2$, textile leather imitates ca. $140 \times 10^6\,\mathrm{m}^2$), whereas the shoe, and the furniture and bag industries consumed about $105 \times 10^6\,\mathrm{m}^2$ and $90 \times 10^6\,\mathrm{m}^2$, respectively. The consumption of leather imitates by the apparel industry amounted to approximately $50 \times 10^6\,\mathrm{m}^2$. The coating materials are mainly poly(vinyl chloride) (50 %) and polyurethane (20 %). The remaining 30 % are made from the raw materials described in Section 3.2. Leather imitates compete with leather in all fields of application, but also have their own areas of application. Leather imitates are produced specifically for their various applications, where they are equal or even superior to leather in many important properties. These include the mechani-

cal properties and the aging characteristics, their permeability to air and water vapor, and their ability to store moisture. The structure and finish of the grain of all types of animal skins can be perfectly reproduced on leather imitates.

The automobile industry uses leather imitates for seats and roofs. The inner lining of doors and the dash boards are often made of carrier-free foam films. Film leather imitates are laminated to a carrier material of wood fibers or plastic by vacuum thermoforming. The film is heated to 140 – 200 °C and formed under vacuum conditions. This processing method requires films with an especially temperature-resistant grain. They can be made either by the reverse method with negatively embossed release paper or by embossing the product at very high temperatures. Compact imitation leather films are often foamed on the reverse side for processing of automobile parts. Textile leather imitates that are not permanently heat deformed can be welded, glued, or sewn. Recent developments deal with the "in-mould decoration" technique where parts are obtained by placing the textile laminate in a mould followed by an injection moulding process step ("direct lamination").

The *shoe industry* mainly uses leather imitates for sport shoes and fashionable footwear. The trend is toward high-quality leather imitates based on polyurethane-coated nonwovens with highly resistant surfaces. The products have the wearing qualities of leather. They have a good storage capacity for moisture and the shoes adjust to the feet on wearing. Leather imitates that are permeable to water vapor are also suitable for lining shoes. Inexpensive shoes and sandals, where permeability to water vapor and moisture storage are not of vital importance, can be made from PVC leather imitates.

The *furniture industry* still uses large quantities of leather imitates, especially for office furniture. In the *bag sector*, leather imitates are required for suitcases, bags, and cases, as well as for covers and small leather articles.

The production of *apparel leather imitates* increased in the 1970s due to the introduction of crinkle leather and suede imitates but has since decreased dramatically. It is, however, still of importance for inexpensive outer garments.

1. Introduction

Lecithin was first isolated in 1850 by GOBLEY, who separated it from egg yolk; it was named lecithin after the greek word for egg yolk, *lekithos*.

Table 1. Composition of soybean lecithin

Component	Content, wt %
Phosphatidylcholine	19 – 21
Phosphatidylethanolamine	8 – 20
Inositol phosphatides	20 – 21
Other phosphatides	5 – 11
Soybean oil	33 – 35
Sterols	2 – 5
Carbohydrates, free	5
Water	1

Later, lecithin was identified as a mixture of many phosphatides. In the 1920s, a process which separates lecithin from crude soybean oil was developed, and today soybeans are still the main source for the mass production of lecithin. Generally, the term lecithin is used to describe soybean lecithin, which is composed mainly of soybean phosphatides and also contains soybean oil. The composition of soybean lecithin is given in Table 1. The uses of lecithin can be divided into foods, feeds, and general industrial uses. Lecithin is used widely in foods because it is both a natural emulsifier and a nutritious food in its own right (see Table 2) and since it gives rise to excellent flavors. In these applications, lecithin is mainly used as an emulsifier, and some treatment of lecithin (e.g., chemical modification and solvent extraction) is carried out. The physiological function of lecithin has been confirmed.

The term lecithin is also used in a chemical sense. In this case, lecithin refers to phosphatidylcholine (PC). The nomenclature of lecithin has been discussed by IUPAC and the International Union of Biochemistry (IUB). The chemical term for phosphatidylcholine was recommended to designate 1,2-diacylglycero-3-phosphorylcholine. The structures of the major phosphatides present in lecithin are shown in the following:

Phosphatidylcholine (PC)

Phosphatidylethanolamine (PE)

Phosphatidylserine (PS)

Phosphatidylinositol (PI)

where R^1 and R^2 represent fatty acid residues.

In this chapter, lecithin without special definition indicates soybean lecithin; the chemical term lecithin refers to phosphatidylcholine (PC).

2. Production

Modern production of lecithin is based mainly on plant seeds, especially soybeans. The quality of lecithin products is determined by the production process and the quality of the raw material soybeans. The flow sheet for a lecithin production process is shown in Figure 1.

Figure 1. Flow sheet for the production of crude lecithin and degummed soybean oil

Seed Preparation. Soybean oil from mature soybeans containing few burnt or fragmented beans gives the highest quality lecithins. Fragmented beans, or beans that have been stored for a long time, result in reduced lecithin yield. Processing of immature beans results in a high chlorophyll content so that the color of the lecithin is dark. This color is difficult to remove by bleaching.

Degumming. Crude oil which contains lecithin is obtained from raw material seeds by compression. The crude oil contains about 2 – 3 wt % of phosphatide. Water (1 – 2.5 vol. %) is added to the crude oil to hydrate the phosphatides. The method that is generally used in the United States involves adding 2 vol % water. The water–oil mixture is then heated at 70 °C for 30 – 60 min in a pipeline agitator that ensures thorough mixing. The oil-insoluble lecithin fraction (a wet gum known as lecithin hydrate) is separated by centrifugation. The gum is then transferred to a holding tank to allow addition of fluidizing and bleaching agents, if required.

Table 2. Concentration of some minor components of soybean lecithin

Component	Concentration, µg/g
Tocopherol	1300
Biotin	0.42
Folic acid	0.60
Thiamin	0.12
Riboflavin	0.33
Pantothenic acid	5.59
Pyridoxine	0.29
Niacin	0.12

Bleaching. To obtain a lighter colored product, hydrogen peroxide and benzoyl peroxide are used to bleach the lecithin. This is carried out either by using a 0.3 – 1.5 % hydrogen peroxide solution instead of water for the degumming process, or by addition of peroxide to the holding tank. The color of a sample is determined using the Gardner method.

Drying. The bleached gum contains 25 – 50 % water. Since the high moisture content encourages the growth of microorganisms, it is necessary to dry the product. The method used is thin-film vacuum drying at a temperature of 80 – 105 °C and a pressure of 3.3 – 4 kPa. The drying is carried out within 1 – 2 min, because high temperatures promote the degeneration (darkening) of lecithin. After drying. it is necessary to cool the lecithin to 55 – 60 °C immediately, because of its instability at high temperature.

Molecular-Membrane Process. A molecular-membrane degumming process has been developed. The molecular mass of the triglycerides is ca. 900, while that of the phosphatides is ca. 800. However, in non-polar solvents such as hexane, the phosphatide molecules of lecithin aggregate to form micelles that have molecular masses of 20 000 – 30 000. In this way, lecithin

can be separated from the triglycerides by a membrane.

3. Commercial Grades of Lecithin

The National Soybean Processors Association (NSPA) trading rules classify commercial lecithins into six grades according to color and viscosity. Fluid lecithin and plastic lecithin are classified by viscosity and each of these is further classified into three classes according to color: natural (unbleached), bleached, and double-bleached. Of these six, only the two unbleached grades are permitted as food additives. The specifications for the six types of lecithin are listed in Table 3.

Table 3. Commercial soybean lecithin specifications

Analysis	Grade		
	Natural	Bleached	Double bleached
Fluid lecithin			
Acetone insoluble, % (min)	62	62	62
Moisture, % (max) [a]	1	1	1
Benzene insoluble, % (max)	0.3	0.3	0.3
Acid value (max)	32	32	32
Color (max) [b]	10	7	4
Viscosity at 25 °C, Pa · s (max)	15	15	15
Plastic lecithin			
Acetone insoluble, % (min)	65	65	65
Moisture, % (max) [a]	1	1	1
Benzene insoluble, % (max)	0.3	0.3	0.3
Acid value (max)	30	30	30
Color (max) [b]	10	7	4
Penetration, mm (max) [c]	22	22	22

[a] Determined by toluene distillation.
[b] Measured on a 5 % solution in mineral oil using the Gardner method.
[c] Using precision cone 73 525 and penetrometer 73 510.

The Food Chemical Codex (FCC) III classifies lecithin products as follows: 1) crude lecithin, 2) fluidized lecithin, 3) highly filtered lecithin, 4) compound lecithin, 5) chemically modified lecithin, 6) fractionated lecithin.

Crude Lecithin generally has high viscosity and is a brown fluid. The NSPA has standardized bleaching, the addition of minerals, and the moisture content.

Fluidized Lecithin is produced by addition of mineral salts, diluents, or fatty acids to crude lecithin. Fluidized lecithin can be handled more easily due to its lower viscosity. Although fluidized lecithins have a low content of acetone-insoluble material, they are graded as high class.

Highly Filtered Lecithin. High-grade lecithin products (e.g., for food) are made by removing the hexane-insoluble material by filtration.

Compound Lecithins. Compound lecithins are produced by blending lecithin with other components. These include oils, polysorbate, monoglyceride, emulsifiers, solvents, and plasticizers; they are generally blended with dry fluid lecithin.

Chemically Modified Lecithin. Lecithins are chemically modified by hydrogenation, hydroxylation, ethoxylation, halogenation, sulfonation, acylation, ozonization, and phosphorylation. Of the chemically modified lecithins, only hydroxylated lecithin is permitted as a food additive at present. Hydroxylation of lecithin increases the hydrophilicity and therefore also the tendency to form oil-in-water emulsions. Hydroxylated lecithins are produced by treating crude lecithin with water and hydrogen peroxide in lactic acid or acetic acid.

Fractionated Lecithin. The composition of crude lecithin, which contains many components, can be changed by fractionation with various solvents.

Acetone Fractionation. Most of the triglycerides and fatty acids can be separated from crude lecithin by acetone fractionation to give oil-free lecithin powders. Oil-free lecithin costs more than ten times as much as regular lecithin. Because it is oil-free, acetone-fractionated lecithin has greater hydrophilicity and increased emulsifying activity.

Alcohol-Extracted Lecithin. Lecithin can be enriched by alcohol extraction. Phosphatidylcholine (PC) is concentrated in the alcohol-soluble fraction. This fraction has increased emulsifying activity for the formation of oil-in-water emulsions. The alcohol-insoluble fraction is rich in the hydrophobic phosphatidylinositol (PI) and therefore favors the formation of water-in-oil emulsions. Phosphatidylethanolamine (PE) is evenly divided between the al-

cohol soluble and insoluble fractions. As alcohol fractionation can change the phospholipid composition, its emulsifying activity is greater than that of acetone-fractionated oil-free lecithin.

Other Fractionation Methods. Lecithins containing large amounts of phosphatidylcholine can be obtained by adsorption and distribution chromatography. For example, products which contain up to 95 % phosphatidylcholine are produced for pharmaceutical use by means of this method.

4. Physical Properties

There are many parameters which characterize the physical properties of lecithin. These are acetone-insoluble matter (AI), acid value (AV), moisture content, hexane-insoluble matter (HI), color, consistency, and clarity. Commercial lecithin is mainly composed of phospholipids (ca. 66 %); the other major components are nonphospholipid compounds such as triglycerides. Since phospholipids are insoluble in acetone, and triglyceride is soluble in acetone, the amount of *acetone-insoluble material* in lecithin corresponds approximately to the phospholipid content.

The *acid value* is measured in miligrams of KOH per gram of lecithin and is determined by acid titration. The acid value is the phospholipid index number as defined in AOCS OM Ja-6-55.

The moisture content of lecithin products is typically less than 1.5 %. The moisture content is determined using the Karl Fischer method.

The *hexane-insoluble matter* (HI) indicates the amount of residual fiber which originates from the production process. The HI measurement is the official Foods Chemicals Codex test method; the HI value must be suppressed to 0.1 %. A high HI level indicates a low grade of lecithin. High-clarity lecithin can be produced by oil filtration to give HI levels of nearly zero. Although the major constituents of lecithin are colorless, the color of commercial lecithin is red-brown or dark-red. The colored components include carotinoid pigments and pigments formed by reaction of amino compounds with phosphatide sugars (Maillard reaction). Phosphatidylethanolamine also contributes to the color through formation of aldol products. The bleaching method is treatment with hydrogen peroxide or benzoyl peroxide. The color is measured by the Gardner method.

Lecithin is classified as plastic or fluid according to its viscosity. The viscosity of fluid lecithin is decreased by addition of fatty acids. Commercial lecithin can be produced as a powder by treatment of the alcohol or acetone fractions. The acetone-insoluble grades consist of a mixture of isolated phospholipids which have either granular or powdered forms. The consistency of alcohol-fractionated lecithins depends on the phosphatidylcholine/phosphatidylethanolamine ratio, which in turn depends on the polarity of the alcohol used, the ratio of lecithin to alcohol, the temperature, and the extraction time.

Lecithin is soluble in oils and is hydrated in water, in which it disperses with formation of an emulsion. The solubility of crude lecithin and of the refined lecithin phospholipids is listed in Table 4.

Table 4. Solubitity of lecithin and its components

	Solubility in		
	Water	Alcohol	Acetone
Soybean lecithin	insoluble	soluble	insoluble
Phosphatidylcholine	soluble	readily soluble	sparingly soluble
Phosphatidylethanolamine	readily soluble	soluble	insoluble
Phosphatidylinositol	readily soluble	insoluble	insoluble

5. Chemical Properties

The chemical properties of lecithin are largely determined by the presence of phosphatides and the fatty acid residues which they contain. The production of modified lecithin has increased because of the need for lecithins with specific properties, such as emulsifiers and wetting agents. The modification methods are either physical, enzymatic, or chemical.

The chemical structure of lecithin remains unchanged upon physical modification. Nevertheless, acetone or alcohol fractionation allows the ratio PC/PE and the amount of phospholipid to be changed, leading to changes in the properties and giving new functions which are lacked by crude lecithin.

Table 5. Quality specifications for lecithin

Specification	Standard			
	FAO/WHO, 8431	FCC, 182 and 1400	EEC, E 332	Japan
Acid value	25 – 35	36	45	40
Benzene insoluble, %	0.3	0.3		0.3
Acetone insoluble, %	62	50	60	40
Peroxide value, meq/kg (max)	10		10	10
Heavy metals, ppm	40	40	40	20
Arsenic, ppm	3	3	3	4
Weight loss on drying, %	2	1.5	2	2

Lecithin can be hydrolyzed enzymatically. On an industrial scale, the enzyme used is phospholipase A 2, which selectively hydrolyzes the fatty acid in the 2 position of the phospholipid and results in the lyso form of lecithin.

Lysolecithin has increased solubility in water and greater emulsifying activity for the formation of oil-in-water emulsions.

Chemical hydrolysis by acids or alkalis is non-specific and affords products that are unsuitably colored.

The reaction of lecithin with acetic anhydride leads to acetylation of the amino group of phosphatidylethanolamine. Acetylated lecithin more readily forms oil-in-water emulsions. The treatment of lecithin with lactic acid and highly concentrated hydrogen peroxide introduces hydroxy groups into the unsaturated fatty acids of the phospholipids. Hydroxylated lecithin more readily forms dispersions with cold water.

6. Uses

Major food applications of lecithin are in chocolate, confectionery, margarine, and baked products. Non-food uses of lecithin include textiles, insecticides, paints, and many others. Lecithin functions as follows: 1) as an emulsifier, 2) as an antispattering agent, 3) crystallization control, 4) viscosity modifier, 5) antisticking agent, 6) wetting agent, 7) dispersing agent, 8) release agent. Usually, the amount used accounts for 0.1 – 1.0 wt % of the final product.

Important food applications of lecithin include baked goods, in which it improves the volume, disperses fats, and acts as an antioxidant, increasing shelf life; chocolate, in which it reduces viscosity and prevents crystallization; its addition to instant foods as a wetting, dispersing, emulsifying, and stabilizing agent; and margarine, in which it acts as an antispattering agent and dispersant.

Non-food uses of lecithin include lubricating oil, fuel oil, leather, textiles, dyes, rubber, soaps, and cosmetics. Lecithin is used in pharmaceuticals as a biological emulsifier and as a source of phosphatidylcholine; in paints as a pigment dispersant and for the stabilization of emulsions; in the production of leather to improve the absorption of fat liquor; and for mosquito control by reduction of surface tension.

Another use is as an additive to animal feeds and as a milk replacer for calves. Lecithin is said to improve the physical properties of the feed and to promote adsorption of some components. Furthermore, because lecithin contains choline and inositol, it promotes the metabolism of oils, fats, and cholesterol in the liver.

Storage. Long-term storage of lecithin at high temperature in the presence of air leads to oxidation of the unsaturated fatty acids, resulting in an off flavor and a black coloration. Therefore, it is necessary to exclude air and to maintain low temperature ($< 20\,°C$) when lecithin is stored for a long time.

Since lecithin contains nitrogen-containing compounds, such as ethanolamine, serine, and B vitamins, water suspensions of lecithin encourage the growth of microorganisms, and therefore

require the addition of preservatives for long-term storage.

7. Quality Specifications and Analysis

Because lecithin compounds (including PC, PE, and PI) are too polar to be subjected to direct gas chromatographic analysis, liquid chromatographic methods are usually used for their analysis. For example, two-dimensional thin layer chromatography is the method most often used, and high performance liquid chromatographic methods are also available.

Some quality specifications for lecithin are listed in Table 5.

1. Introduction

The leucoesters of vat dyes are formed by esterifying each hydroxyl group of the leuco-form of the parent dye with a di- or polybasic acid.

Their technical value lies in their greatly improved leveling properties compared with the parent leuco dye and their suitability for use on a wide variety of fibers.

The only leuco esters of vat dyes available at present are the sodium or potassium salts of the sulfuric acid esters; other esters (e.g., of phosphoric or 3-sulfobenzoic acid) have no practical application. BADER, SUNDER and VAUCHER developed a method of synthesizing the leuco disulfuric ester of indigo (patented for Durand & Huguenin in 1921 [2], [3]). They adapted VERLEY's method for sulfating phenols by using chlorosulfuric acid ($ClSO_3H$) in pyridine [4] to esterify isolated, dry leucoindigo:

Indigosol O (Durand & Huguenin) C.I. 73002
Anthrasol O (Hoechst) [3875-70-5]

A more generally useful method that avoids isolation of the leuco dye was devised by chemists at Morton Sundour Fabrics (the parent company of Scottish Dyes) and patented in 1924 [2], [5]. This process was first used on a production scale in 1925 to prepare the leuco disulfuric ester of 16,17-dimethoxyviolanthrone as its disodium salt [2], [6] (→ Anthraquinone Dyes and Intermediates, Chap. 2.12.8.).

Soledon Jade Green X (Scottish Dyes, later ICI) C.I. 59826
Anthrasol Green IB (Hoechst) [2538-84-3]

The Scottish Dyes process is the basis of most manufacturing methods. Other, more recent, methods have limited or no commercial application. Leuco esters of vat dyes have declined significantly in commercial importance in recent years (see Chap. 6).

2. Manufacturing Methods Using Sulfur Trioxide–Amine Addition Compounds

2.1. The Durand & Huguenin Process for Indigoid Dyes

In the developed prototype process isolated, dry leucoindigo is esterified by using chlorosulfuric acid in dimethylaniline.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_299

Monochlorobenzene or excess dimethylaniline is used as solvent, and esterification is effected at 50 – 60 °C. The product (Indigosol O) is isolated as the disodium salt [7], [8]. This method, requiring isolation of the leuco vat dye, is useful primarily for indigoid and thioindigoid dyes.

2.2. The Scottish Dyes Process for Anthraquinone Dyes

The Scottish Dyes process avoids isolation of unesterified leuco forms which, for most anthraquinone and related dyes, are unstable and often very soluble. The overall reaction formally proceeds as follows using a *para*-quinone moiety:

In this method, the dry, powdered vat dye is stirred into a cooled solution of chlorosulfuric acid in excess pyridine and reduced by addition of a metal powder (usually iron or copper). Esterification proceeds concurrently with reduction, but not necessarily at the same rate. Usual reaction temperatures are 40 – 60 °C. Pyridine acts as a solvent, a hydrogen chloride acceptor, and a sulfur trioxide carrier:

The reaction mixture is then poured into aqueous alkali and clarified; pyridine is removed and the product isolated as its sodium or, if the dye is relatively insoluble, its potassium salt. (Salts of lithium or ethanolamine have been proposed but not used to any extent) [9], [10].

The patent literature covers the use of many metals and alloys for reduction: iron, copper, aluminum, zinc, brass, and bronze.

Although widely applicable, this process does not work well with all vat dyes, particularly 1,4- and 1,5-disubstituted anthraquinone derivatives, because in these cases overreduction can occur, for example, with formation of anthranol esters [11] (loss of one hydroxyl group):

These products, which are usually not very soluble, do not regenerate on the fiber to the parent vat dye.

Some 1,4-disubstituted anthraquinone derivatives can be used satisfactorily. An example is

Anthrasol Brown IBR (Hoechst) C.I. 70801 [*23725-15-7*]
Soledon Dark Brown 3R (ICI)

made from Indanthren Brown BR (Anthraquinone Dyes and Intermediates).

2.3. The IG Farben (Hoechst) Process for Indanthrone Dyes

Direct esterification of indanthrone dyes produces a very insoluble diester rather than the desired tetraester. Hence, the following method (illustrated here by its most important application) was developed by IG Farben [10], [12], [13]:

Indigosol (Anthrasol) Blue IBC (Hoechst)
Soledon Blue 2RC (ICI) C.I. 69826 [*2519-28-0*]

Lead(IV)oxide is a satisfactory and widely used oxidant, although other agents and anodic oxidation have been used [15], [16].

2.4. Miscellaneous Processes [17]

The ICI Dimethylformamide and Related Processes. Addition compounds of *N,N*-dialkylamides (particularly *N,N*-dimethylformamide) with sulfur trioxide can be used as the esterifying agents, with the amide itself (or a solvent such as dichloroethane) as the reaction medium [18].

The Durand & Huguenin Mixed Amine Process. Pyridine in the Scottish Dyes process can be replaced by a mixture of a strong tertiary alkylamine (e.g., *N,N*-diethylcyclohexylamine) and a weak tertiary amine (e.g., α-picoline). This combination enables esterification to proceed rapidly, whereas reduction is relatively slow, thereby minimizing overreduction [11], [19].

The American Cyanamid All-Aqueous Process. American Cyanamid proposed the use of addition compounds of sulfur trioxide and tertiary alkylamines such as *N*-ethylmorpholine as esterifying agents in an *aqueous* medium. If these agents are used in suitable excess, they react rapidly with the leuco vat dye in alkaline solution without excessive decomposition [16], [21].

3. The ICI Process Using Chlorosulfonate as Esterifying Agent

The ICI process is unusual because it does not employ an amine – sulfur trioxide addition compound as esterifying agent, but rather, a chlorosulfonate. Typically, methyltriethylammonium chlorosulfonate is used in a solvent such as acetonitrile. The chlorosulfonate ion is highly reactive and effects rapid esterification at low temperature [17], [20].

4. Properties

Stability. All leuco esters of vat dyes are to varying degrees, sensitive to heat, moisture, acid, atmospheric carbon dioxide, and light. They are, however, quite stable to alkaline hydrolysis.

Any local action of acids leads to hydrolysis of the ester groups, releasing more acid which can finally lead to total decomposition of the contents of a package. Various stabilizing agents are added during formulation to minimize this risk [22]. Urea, which also acts as a solubilizer, is particularly useful.

Drying is carried out under mildly alkaline conditions either at low temperature (ca. 50 °C) or by spray drying.

Storage should be in opaque, airtight packages away from sources of heat, including direct sunlight.

Solubility. The solubility of various leuco esters varies considerably. Sufficient solubility is particularly important in textile printing; thus, solubilizing agents such as urea, diethylene glycol, or thiodiglycol are usually incorporated in the print pastes.

Substantivity. The relative order of substantivity is generally the same as that of the sodium salts of the leuco forms of the parent vat dyes. However, the absolute values are always lower because of the presence of the sulfate group. This gives these dyes their most important property: improved leveling behavior which is required especially when pale shades are being dyed.

With the exception of Anthrasol Blue IBC, the anthraquinone dyes, as a rule, have distinctly higher substantivity than indigoid and thioindigoid dyes.

The best uptake of dye on the fiber is usually at 25 – 30 °C, but for a few anthraquinone dyes (e.g., Anthrasols Green IB and Brown IBR) the uptake is best at 50 – 70 °C.

Ease of Regeneration (Development). Dyes, once on the fiber, are normally regenerated with sulfuric acid and sodium nitrite. Most regenerate easily in a cold bath; a few require a temperature of 70 °C.

Lightfastness of the Developed Dye. Under standard test conditions on cellulose, most anthraquinone dyes are of very high fastness, 7 – 8 on the numerical scale. The indigoid and thioindigoid types generally have distinctly lower lightfastness.

5. Uses

Dyeing. Leuco esters of vat dyes are remarkably versatile and have been used to dye wool (perhaps the first application), silk, cellulose, polyester, cellulose – polyester blends, and even polyamide, although their lightfastness is relatively poor on the last. To date their main use has been for all-cellulose fabrics or cellulose – polyester blends. Dyeing of cellulose fabrics can be carried out by conventional exhaust and padding methods, with development usually by sulfuric acid and sodium nitrite. Cellulose – polyester blends are normally dyed by one of three methods: (1) the high-temperature one-bath method, (2) the Anthrasol – thermosol develop method and (3) the pad – thermosol cold-develop process [17], [23]. The last method is used when these dyes are applied in conjunction with disperse dyes.

Textile printing. The three steps involved in printing textiles are application of the dye in its soluble leuco form, dyeing onto the fiber, and finally regenerating (developing) the parent, insoluble vat dye. Dyeing must take place before regeneration.

Several methods are available for developing the printed dye, two of which are particularly important. These are the nitrite process using sodium nitrite (in or padded onto the print paste) with sulfuric acid as the oxidizing system, and the chlorate process using either sodium chlorate and ammonium thiocyanate (the sulfocyanide process) or ammonium chlorate [17].

The print pastes must be protected from sunlight and acidity to avoid premature development.

6. Economic Aspects

Development of modern textile application methods, together with associated improvements in the formulation of vat dyes, has reduced the need for their solubilized analogues. In addition, the development of reactive dyes with good color fastness has reduced the demand for indigoid and thioindigoid vat dyes and their solubilized equivalents. This, together with worldwide rationalization of the dye industry, has virtually elucidated manufacture in the Western world.

Although well over 60 of these dyes have been made, the core palette [7], [13] throughout the duration of their existance remained largely unchanged.

The products which survived for the longest time are the anthraquinone dyes with the highest light- and all-round fastness. Examples of these, already discussed, are Anthrasol Blue IBC, C.I. 69 826; Anthrasol Green IB, C.I. 59 826; and Anthrasol Brown IBR, C.I. 70 801.

1. Occurrence and Functions

Lignin is one of the three major constituents of vascular plants, the other two being cellulose and hemicelluloses. The name lignin is derived from the Latin word *lignum* meaning wood. After cellulose, lignin is the most abundant natural (terrestrial) organic polymer. Its content is higher in softwoods (27–33 %) than in hardwoods (18–25 %) and grasses (17–24 %). The highest amounts of lignin (35–40 %) occur in compression wood on the lower part of branches and leaning stems of conifers [1, 2]. Lignin does not occur in algae, lichens, or mosses [3], whereas the "lignins" of bark differ in their structure from typical wood lignins [4].

Lignin is a randomly branched polyphenol, made up of phenylpropane (C_9) units, rendering it discernible from the other two major wood components by its UV absorption maximum at 280 nm. Figure 1 shows a typical UV microscopic imaging profile on a microtome cut of an individual spruce wood fiber [5]. Novel instruments can as well provide color-coded 2D or 3D plots, showing the lignin distribution over the cross-section of fibers [6]. The highest lignin concentration (≈ 70 %) is found between adjacent cell walls (middle lamella) and at the cell corners, while it is much lower (≈ 20 %) across the secondary wall. However, due to the much larger volume of the secondary wall, most lignin (≈ 80 %) is located in the secondary wall of the wood cells.

Figure 1. A) Black spruce earlywood

In accordance with its distribution, lignin performs three important functions in the xylem tissue that are essential to the life of plants: Due

to its lipophilic character, lignin decreases the permeation of water across the cell walls, that consist of cellulose fibers and amorphous hemicelluloses, thus enabling the transport of aqueous solutions of nutrients and metabolites in the conducting xylem tissue. Secondly, lignin imparts rigidity to the cell walls and, in woody parts, together with hemicelluloses, functions as a binder between the cells generating a composite structure with outstanding strength and elasticity. Finally, lignified materials effectively resist attacks by microorganisms by impeding penetration of destructive enzymes into the cell walls.

The above mentioned functions of lignin are impressively demonstrated by the strength of the trunks of giant redwoods (*Sequoia*) in California, growing up to more than 100 m, supporting crown structures of several tons in weight for thousands of years, unparalleled by human constructions.

2. Structure and Biosynthesis

After cell growth has ceased, lignin is formed by a dehydrogenative polymerization of three *p*-hydroxycinnamyl alcohols (monolignols): i.e., *p*-coumaryl (**1**), coniferyl (**2**), and sinapyl alcohol (**3**) (Fig. 2), which are formed from D-glucose via shikimic acid [7]. It has to be mentioned that in lignin chemistry the designation of the carbon atoms does not follow the IUPAC nomenclature. The aromatic ring is numbered assigning the phenolic OH group to position 4. The propane side chain is labeled with Greek letters, starting from the benzylic carbon, termed α carbon. The phenylpropanoid monomers are oxidized to phenoxy radicals by hydrogen peroxide in the presence of peroxidase. The unpaired electron of the phenoxy radical is delocalized over the aromatic ring and the conjugated olefinic double bond of the side chain, the highest density of the unpaired electron being at the β-carbon atom, C-5, C-1, and O-4, as illustrated for coniferyl alcohol in Figure 3. Random recombination of two monomeric phenoxy radicals leads to dilignols, which are further oxidized to oligolignols and finally to the polymeric lignin. The most important structural units and their designation are depicted in Figure 4.

Figure 2. Monomeric lignin precursors

In order to prove this pathway Freudenberg and his group carried out tracer experiments with carbon-14 labeled D-glucose, phenylalanine, coniferyl alcohol, and D-coniferin [7]. In addition they performed in vitro model studies by dehydrogenation of coniferyl alcohol with peroxidase and hydrogen peroxide, obtaining polymers which were not identical but rather similar to lignin [7]. The resulting products were called dehydrogenation polymers (DHP) and have been intensively used as a lignin polymer model by many research groups.

The random polymerization by recombination of phenoxy radicals explains why lignin — in contrast to most other natural polymers such as proteins, polysaccharides, nucleic acids, and natural rubber — has an irregular structure and is optically inactive, though carbon atoms α and

Figure 3. Dehydrogenation of coniferyl alcohol (**2**) yielding phenoxy radicals

Figure 4. Most important structural units of lignin

β in the side chains of the phenylpropane structural units are asymmetric. However, it has to be kept in mind that the last polymerization step takes place within the secondary cell wall of differentiated wood cells in close contact with partly crystalline cellulose fibers, so that the aromatic nuclei in lignin may partly be aligned tangentially to the secondary wall [8]. Recently (in the early 2000s) a new hypothesis has evolved, postulating that the synthesis of lignin might be at least partly controlled by dirigent proteins. Such proteins are involved in the polymerization of lignans, a group of oligomeric products which belong to the extractives of lignocellulosic plants. This hypothesis is discussed rather intensely and summaries of the pros and cons have been published by the main protagonists [9, 10].

The random coupling reaction, which is still the most widely accepted concept, results in a three-dimensional, amorphous polymer without a regular structure or repeating unit. Accordingly, no definite lignin structure can be determined although several schemes have been proposed as a statistical structural model for various plant species. A first concept for spruce lignin was developed by Freudenberg [7] based on 18 C_9 units, of which 2.5 (units 2, 3, 5)

are coumaryl, one a syringyl (3,5-dimethoxy-4-hydroxyphenyl) (unit 16), and 14.5 guaiacyl (3-methoxy-4-hydroxyphenyl) units (Fig. 5). A structural scheme of beech lignin was proposed by NIMZ consisting of 25 structural units, of which six (5/6, 9/10, 24/25) are partly replaced by the dilignol units enclosed in brackets (Fig. 6). The concentrations of the latter units are below 4 %. The scheme shows a representative section of a ten to twenty times larger beech lignin molecule, in which ten different interunit bond types are randomly distributed. The relative amounts of interunit linkages for the two lignin structures are listed in Table 1 [11]. The data show as well that the calculated C_9 formulas are in good correlation with experimental data for isolated lignins. The most abundant interunit linkages in both schemes are the β-O-4 linkages. It is the concentration of these linkages in which lignins typically differ from other polyphenols occurring also in plant materials. During the lignification process the quinonemethide can also react with hydroxyl or carboxyl groups of polysaccharides forming covalent ether and ester bonds in the α-C position. These covalent bonds make it difficult to obtain lignin without carbohydrate impurities for both analytical and technical purposes. For this close association of lignin and carbohydrates the term lignin carbohydrate complex (LCC) has been coined [12].

Although the structures in Figures 5 and 6 do not include some new features such as the dibenzodioxocin structure (Fig. 3, **12**) discovered in the 1990s [15], they are still good models to describe the fundamental differences of softwood and hardwood lignins. According to the high proportion of guaiacyl units softwood lignins are called guaiacyl lignins (G-lignins), while hardwood lignins are termed guaiacyl–

Figure 5. Constitution of spruce lignin after FREUDENBERG [7]

Table 1. Proportions (%) of interunit linkages, functional groups and elementary composition per C_9 unit of spruce and beech lignin according to structural schemes in Figures 5 and 6

Bond types, functional groups and elementary composition of C_9 unit	Spruce lignin	Beech lignin
β-O-4	39–48	32–37
α-O-4	11–16	28–32

Figure 6. Constitutional scheme of beech lignin after Nimz [11]

syringyl lignins (GS-lignins). Grass lignins additionally contain *p*-hydroxyphenyl (coumaryl) units (GSH-lignins).

Accordingly, hardwood lignins have the highest methoxy values with 1.21–1.52 per C_9 unit, followed by softwood lignins with 0.80–1.01 and grass lignins with about 0.6–0.9 [16]. However, the low methoxy values of grass lignins may also be caused by substantial amounts of *p*-coumaric acid, linked to the γ-carbon atoms of grass lignins via ester bonds [17]. The methoxy group content of compression wood MWL from larch (*Larix leptolepis*) was found to be 0.2 per C_9 unit lower than that of normal wood MWL [18]. From the comparison of the carbon-13 NMR spectra of acetylated compression wood MWL with those of acetylated GSH- and H-DHPs (*p*-hydroxyphenyl dehydrogenation polymers), compression wood lignin was classified as a guaiacyl-*p*-hydroxyphenyl (GH)-lignin [19].

Variations in the methoxy group contents cause changes in the constitution of the lignins. As shown in Table 1 the proportions of α-O-4 and β-1 interunit linkages in beech lignin are significantly higher than those in spruce lignin, while the content of 5–5 and 4–O–5 linkages is lower, meaning that softwood lignins are more condensed than hardwood lignins and hardwoods may be more easily delignified than softwoods, agreeing with the differences in the chemical properties of hardwood and softwood lignins. Consequently, compression wood lignins have the highest level of condensation with the lowest solubility and degradability. A review with almost 700 references on the history, chemistry, and technology of lignin is given in [20].

3. Physical Properties

Solubility. As a branched polymer, native lignin is insoluble in all neutral solvents at room temperature. At temperatures above 100 °C or in alkaline solvents native lignin is partly dissolved as a result of degradation reactions. For isolated or technical lignin the solution properties vary depending on the isolation or production process and sample purity. Milled wood lignins are soluble in dioxane and acetone, containing 5–10 % water, as well as in dimethylformamide and pyridine. Lignosulfonates can be dissolved in water, while all isolated lignins are soluble in alkali. Most lignins can be solubilized in organic solvents such as dimethyl sulfoxide, dimethylformamide, dioxane, and pyridine at least for analytical purposes.

Molar Mass. The molar mass of lignin in situ is unknown and that of isolated lignins depends on the conditions of isolation. In general the molar mass determination of lignins with various methods show a large deviation (see Section 6.5). For spruce milled wood lignin an average molar mass (M) of 11 000 g/mol has been estimated by ultracentrifugation [21], corresponding to a weight-average degree of polymerization of approximately 60 C_9 units. For the most important commercial lignins from the kraft, soda, and sulfite pulping process molar masses in a range between 3 000 and 20 000 g/mol and polydispersities between 2 and 12 have been reported, while the intrinsic viscosities were in a range from 0.04 to 0.08 dL/g. The exponent a from the Mark–Houwink–Sakurada equation varies between 0.1 and 0.5, which is in the range between an Einstein sphere ($a = 0$) and a compact coil ($a = 0.5$) [22, 23].

Thermal Properties. Lignin is an amorphous thermoplastic polymer. The glass transition temperature T_g of lignin is strongly affected by moisture content and hydrogen bonding, a phenomenon of great importance for the wood processing industry. By dynamic mechanical thermal analysis the T_gs of native lignins in wood were calculated resulting in lower values in hardwoods (65-85 °C) than in softwoods (90-105 °C). For isolated lignins the T_g values are higher and show deviations according to the raw material, production process, and measurement procedure: MWL lignins: 110 to 160 °C, kraft lignins: 124–174 °C, steam explosion lignin: 113–139 °C [24]. The effect of moisture was demonstrated for an isolated periodate lignin which had a T_g of 195 °C when dry and a T_g of 90 °C when containing 27 % water [25]. Thermal properties are as well depending on molar mass. On fractionated kraft lignins the fraction of lowest molar mass (M 620 g/mol) had a T_g of only 32 °C while at highest molar mass (M 180 000 g/mol) T_g amounted to 173 °C. A similar tendency was observed for the temperature of

start of decomposition which increased with molar mass from 181 to 238 °C [26]. The calorific value of lignin depends on the purity of the sample. The dry matter of the black liquor from the kraft process has a value around 23.4 MJ/kg [1].

4. Chemical Properties

Besides ketone and aldehyde groups, the most reactive functional groups in lignin are the phenolic groups, the benzyl alcohol (α-OH) and noncyclic benzyl ether groups (α-O-4), which under acidic and alkaline conditions are prone to condensation reactions. From an industrial standpoint the reactions of lignin in pulping processes are most important since these reactions influence not only the pulping process itself but the structural features of technical lignins obtained as by products.

4.1. Kraft Pulping

The leading technical pulping process with sodium hydroxide and sodium sulfide is called kraft pulping. The word "kraft" originates from the German word "Kraft" (strength), meaning the strength of the obtained kraft pulps in comparison to that of sulfite pulps.

As a main reaction of the kraft process moieties with free phenolic groups are converted into quinonemethide groups (**15**), which add hydrogen sulfide ions at the α-carbon atoms (Fig. 7). The thus formed benzylthiolate anion (**16**) loses its β-phenolate anion in a neighboring displacement reaction. The units with free phenolic groups thus created may again form quinonemethides and add hydrogensulfide ions, if their α-carbon atoms are bonded to hydroxyl or noncyclic ether groups. At the high reaction temperature the sulfur from compound (**17**) is partly split off. Especially in the last stage of the kraft process carbon-carbon bonds can be formed between lignin units, a reaction which is referred to as "condensation". This results in structures which are very difficult to cleave in further process stages. Furthermore, the hydrogensulfide ions lead to demethylation reactions and subsequently to the formation of methyl mercaptan which resulted in former times in odor problems in the mills. An extensive review on the reactions and technology of pulping processes is given in [27].

Figure 7. Mechanism of kraft cooking

4.2. Sulfite Pulping

In the technical sulfite pulping processes wood is usually reacted with calcium (pH ≈1-2) or magnesium sulfite (pH ≈3-5) at ca. 125 to 150 °C for 3 to 7 h. The three major reactions occurring simultaneously are sulfonation, hydrolysis, and condensation. The dissolution of lignin in aqueous solution is mainly caused by the introduction of hydrophilic sulfonic acid groups at the α-carbon atoms (Fig. 8). In the *sulfurous acid* process at pH 1–1.6 and in the *acid sulfite* process at pH 1.8–3.1, benzyl alcohol and benzyl ether groups in lignin form benzylium ions (**20**), that preferably add nucleophilic sulfite ions, but to some extent may also lead to condensation products (**21**) [28, 29]. The degree of condensation may be less in the *bisulfite process* at pH

4.5 and the *bisulfite-sulfite* process at pH 7. The β-O-4 bond is rather stable under acidic conditions. Some sulfite processes operate under neutral or alkaline conditions using sodium or ammonia as base. In these processes β-O-4 bonds can be cleaved as well depending on the reaction conditions. The spent sulfite liquor, besides degraded hemicelluloses contains lignosulfonic acids (**22**).

Figure 8. Mechanism of sulfite cooking

4.3. Other Pulping Processes

Especially in countries with small wood resources the soda process is used for the production of pulp from annual plants applying only sodium hydroxide as a reaction chemical. In this process only α-aryl ether bonds in phenolic lignin units are effectively cleaved [29]. The addition of the redox catalyst system anthrahydroquinone/anthraquinone can improve the delignification when raw materials with higher lignin content are processed. Anthrahydroquinone can catalyze the cleavage of lignin in a similar manner to sulfide, improving especially the cleavage of β-O-4 linkages [30]. It can be applied in all alkaline processes such as kraft or alkaline sulfite pulping.

A large number of pulping processes based on organic solvents have been investigated over the last decades and were summarized under the term "organosolv" processes. Some were based on organic solvents (especially methanol and ethanol) with and without addition of catalysts while others were applying organic acids (mainly formic and acetic acid) [31, 32]. Up to now none of these processes has been implemented in industry. Nevertheless, in many papers on new applications of lignin still organosolv lignins from former pilot plant trials are used as a raw material, especially when a sulfur-free lignin is required.

Steam explosion or steam refining is a process route for the production of fibers from wood or straw. These processes are often catalyzed autohydrolytically by organic acids liberated from the hemicelluloses of hardwoods or straw. During steam explosion a part of the lignin ($\approx$10–15 %) is rendered water-soluble while the rest can be extracted with dilute sodium hydroxide solution. During the steam treatment an acid-catalyzed hydrolysis of aryl ether linkages takes place while on the other hand homolytic cleavages occur. At high reaction severity a recondensation of lignin can occur as well. Accordingly steam explosion lignins have higher molar masses than sulfite, kraft, or organosolv lignins. Steam explosion lignins might become interesting in the future, because this process is the first step for saccharification of lignocelluloses for glucose or ethanol production, a process route which is currently under discussion as a source for bioenergy and fuel [31, 33] (the whole issue of [33] deals with steam explosion.)

4.4. Pulp Bleaching

Unbleached pulps still contains between 1.5 and 6 % of lignin. Since the residual lignin is intensively colored it has to be removed in order to produce pulps with high brightness and brightness stability. Previously chlorine and chlorine dioxide were major bleaching chemicals lead-

ing to toxic chlorinated phenols in the bleaching effluents (measured as adsorbable organic halogen (AOX). In order to reduce these effluents, chlorine (C) was almost completely and chlorine dioxide (D) partly replaced by alkaline oxygen (O), hydrogen peroxide (P), and ozone (Z), leading to *totally chlorine free* (TCF) or *elemental chlorine free* (ECF) bleached pulps. In the production of ECF pulps chlorine dioxide is still applied, but no gaseous chlorine. In the beginning of these developments it was often assumed that TCF bleaching should be the long-term goal for an environmental-friendly industry. However, it has been shown that a modern ECF sequence can be operated with very low AOX levels and accordingly ECF is now the dominating technology for modern pulp mills [34].

4.5. Yellowing Reactions

In the presence of alkali and oxygen or in daylight lignin shows an intense discoloring, which is observed by the yellowing reaction of paper, paper products, and wood. A major reaction pathway is the absorption of ultraviolet light by the α carbonyl group leading to a phenoxy radical which reacts subsequently with oxygen to form quinoid chromophores (Fig. 9).

Figure 9. Main reaction pathway of photo yellowing

The photoyellowing is a rather complex process which was recently summarized in [35]. For applications of lignin the sensitivity to UV light has to be considered being a potential problem for product stability or a positive feature when UV absorbing properties are required.

5. Commercial Lignins

Up to now commercial lignins are exclusively obtained as byproducts from the chemical pulping industry. The kraft process is the dominating technology with about 89 % of the total production capacity while in 2000 the share of the sulfite process had declined to only 3.7 %. Nevertheless, lignosulfonates from sulfite processes are still of major importance for the application of lignin as industrial products. About 10 % of the total pulp production is based on nonwood plant materials like bast and leaf fibers, straw, sugar cane bagasse, or bamboo. These materials are easier to delignify and are mainly produced by the soda process. They are especially important raw materials in countries with small wood resources like India and China [36]. In former times these lignins were not commercially available. Recently a plant for lignin recovery from nonwood soda pulping has been installed which claims an annual production capacity of 10 000 t sulfur-free lignin [37] and accordingly soda lignins might become an alternative in the future. In 1998 some 50×10^6 t of lignin were produced in the western hemisphere as a byproduct of pulp, less than 2 % of this amount was isolated and sold. Kraft lignin, making up some 95 % of the totally produced lignin, is predominantly burnt to cover the energy demands of kraft mills and the recovery of caustic soda in the mill. Most of the commercially used kraft lignin is sulfonated to water-soluble lignosulfonates. Excluding the former Soviet Union, lignosulfonate production capacity in 1998 was estimated to be about 975 000 t/a with some new capacities under construction in South Africa [38].

The lignins are contained in the pulping liquor as a mixture with other wood degradation products with strongly fluctuating composition depending on the process and the raw material. Typical compositions of pulping liquors from hardwoods and softwoods obtained by the sulfite and kraft process are summarized in Tables 2 and 3 [39]. Kraft lignins are preferably obtained by precipitation from “black liquors” with mineral acids or carbon dioxide, whereas crude lignosulfonates are partly used directly as “spent

sulfite liquors". The isolation of lignosulfonates can be achieved by addition of excess lime, by treatment with a long-chain alkylamine and extraction, or by ultrafiltration. In order to produce high-purity lignosulfonates a chemical destruction of sugars, or fermentation treatments can be included into the refinement procedure [38]. The sulfur contents of lignosulfonates (4–8 %) are higher than those of kraft lignins (1–1.5 %). Due to the sulfonate groups the lignosulfonates show good solubility in water over the entire pH range but are insoluble in many organic solvents. Kraft lignins are not soluble in water but in alkali at pH > 10.5. They are as well soluble in many organic solvents. The molar masses of lignins are difficult to determine in a reliable way and often results in controversial discussion of data. Furthermore molar masses depend strongly on the pulping conditions. In most cases the molar masses of lignosulfonates are higher compared to kraft lignin and even values up to 60 000 g/mol have been reported [40], although lower data are found for most samples [22, 23]. For Kraft lignins the data are mostly below 10 000 g/mol [22, 23, 39].

Table 2. Example for the composition of spent sulfite liquors from softwood and hardwood [39]

Component	Percentage of total solids	
	Softwood	Hardwood
Lignosulfonate	55	42

Kraft lignins contain larger amounts of phenolic hydroxyl, carboxyl, and catechol groups than lignosulfonates and are more likely to possess some unsaturated side chain structures. For certain application lignins can be further modified in order to improve the dispersing, complexing, or binding properties. These treatments can be sulfonation, sulfoalkylation, desulfonation, oxidation, carboxylation, amination, crosslinking, graft polymerization, and various combinations of the previous methods. Most of the kraft lignins are subjected to sulfonation either with sodium sulfite at 150–200 °C or oxidative with oxygen and sulfite. They can also be sulfomethylated with sulfide and formaldehyde at temperatures around 100 °C. Lignosulfonates are mostly obtained as magnesium, calcium, ammonium, or sodium salts [38 – 41].

Trade Names: A large variety of trade names and products exists. However, most of these products are marketed by two companies, Mead-Westvaco Speciality Chemicals and Borregaard-LignoTech, where the first company is dominating the kraft lignin and the latter the lignosulfonate market. Some trade names are listed below:

Unsulfonated kraft lignin	Indulin
Sulfonated kraft lignin	Polyfon, Reax
Lignosulfonates	Ameri-Bond, Borresperse, Borresol, Collex, Diwatex, Dustex, Dynasperse, Kelig, LignoBond, LignoSol, Marasperse, Norlig, Ufoxane, Ultrazine, Wafex, Wanin, Zewa
Soda lignin	Protobind, Biosurfact

6. Analysis

Due to its complicated structure the analysis of lignin is very difficult. For the pulp industry the analysis of lignin contents in pulps and raw materials is specified, while for technical lignins no well-defined industrial standards exist. For these reasons it is difficult to obtain reliable, detailed information on technical products. Due to this situation the following information can provide only a small insight into the field of lignin analysis. A review of most classical techniques for lignin analysis is given in [42].

6.1. Detection and Quantification

The easiest methods to detect lignin in plant materials are color reactions. However, those tests can be perturbed by some polyphenolic plant extractives. In the *Wiesner reaction* the material is treated with phloroglucinol in hydrochloric acid, leading to a purple conjugated quinone [43], formed between phloroglucinol and cinnamyl aldehyde groups in lignin. The reaction is positive with all lignins, but is weak with hardwood lignins with high contents of syringyl units.

For the *Mäule test* [44] lignified material is treated with a 1 % potassium permanganate solution, followed by washing, a treatment with 12 % hydrochloric acid, and a final moistening with aqueous ammonia. With hardwoods an intensive purple-red color is produced, while with softwood lignins the color is an indefinite brownish shade. The chromophores are probably chlorinated quinones.

The quantitative determination of lignin in plants most commonly used, the *Klason procedure*, is based on the observation that cellulose and hemicelluloses are hydrolyzed by concentrated sulfuric acid to soluble sugars while lignin is condensed to an insoluble cross-linked polymer which is recovered by filtration on a filter crucible and can be gravimetrically determined. This procedure is a standard test for raw materials in the pulp industry [45].

Another method for the quantitative determination of lignins in wood uses the solubility of wood in a mixture of acetyl bromide and acetic acid [46]. After removal of the reagent, the absorbance of the resulting solution is measured at 280 nm. A detailed overview on all analytical methods for the determination of lignin in raw materials as well as in pulps is given in [47]. A critical comparison of several methods including not only wood and straw but various agricultural residues was presented in [48].

6.2. Isolation

The complete isolation of unchanged lignin from wood is not possible, due to its intimate merging with cellulose and hemicelluloses in the secondary walls of wood cells. Lignin has to be degraded before extraction and accordingly the structure depends on the conditions of isolation. The most common procedure for structural and analytical purposes is production of *milled wood lignin* (MWL), also called *Björkman lignin* [49]. In the isolation procedure preextracted, dry wood meal is milled for, e.g., 30 days in a vibratory ball mill under a nonswelling solvent (toluene). In the subsequent extraction step with dioxane – water (9:1) up to 50 % of the lignin can be isolated from conifer wood which can be further purified in order to reduce carbohydrate impurities. Further methods for the isolation of lignins from pulps and pulping liquors are summarized in [42].

Recently it has been proposed to dissolve ball-milled cell wall material in dimethyl sulfoxide and tetrabutylammonium fluoride or *N*-methylimidazole. The product mixture of lignin and polysaccharides can be directly acetylated in the solution and allows further analyses, e.g., by 2D NMR techniques. Although this is no isolation procedure in the strict sense it can serve the same purposes for analytical techniques. A major advantage is that a higher lignin yield than in traditional isolation procedures is obtained [50].

For pulp fibers a method has been developed which is based on the enzymatic saccharification of polysaccharides and allows recovering of the undissolved lignin residue from the aqueous solution [51].

6.3. Spectroscopic Methods

UV Spectroscopy. The aromatic structure of lignin gives rise to a strong absorption maximum at 280 nm, while wood carbohydrates are transparent in the near-ultraviolet range. As, according to the Lambert – Beer law, the absorption of UV light by dissolved lignin is proportional to its concentration, UV absorption can be used for quantitative determination of lignin in solution or as a detection method in liquid chromatography [52]. In alkaline solution, the UV spectrum of lignin shows a bathochromic shift and hyperchromic effect, due to the formation of phenolate anions. An alkaline ionization difference spectrum ($\Delta\epsilon_i$) is obtained by subtracting the UV spectrum of the neutral solution from that of the alkaline solution. $\Delta\epsilon_i$ -Spectra are often used to obtain information on the amount of phenolic

hydroxyl groups. These spectra show as well specific absorption peaks for conjugated (carbonyl and olefinic) groups in lignin, which thus can be determined semiquantitatively [53, 54]. The UV absorption can be used also in the solid state for UV microscopy on microtome cuts (Fig. 1).

FTIR spectra of lignins are usually measured on finely ground solid samples dispersed in potassium bromide pellets. In solution the lignin spectra are influenced by strong interfering absorption bands of the solvents, i.e., semiquantitative work can be carried out better with KBr pellets using controlled pressing conditions and weight ratio of lignin to potassium bromide. The assignment of infrared absorption bands of lignins has been reviewed in [55] and [56].

NMR Spectroscopy. Of all physical methods, NMR spectroscopy provides by far the most complete information on the chemical structure of lignins. The assignment of some 40 signals in the ^{1}H broad-band decoupled carbon-13 NMR spectra of spruce and beech MWLs and DHPs as well as their acetates has been achieved in the early 1970s by comparison with the spectra of more than 50 lignin model compounds [57]. By now ^{1}H and ^{13}C shifts for a variety of model compounds have been determined and a large database is provided by the U.S. Dairy Forage Research Center in Madison, Wisconsin. This database is continuously updated and available free of charge in the internet [58]. Although solid-state NMR (^{13}C cross-polarization magic angle spinning (CP-MAS) NMR) spectra of lignin have been frequently recorded [59], the solution NMR techniques have by far the higher importance due to their higher resolution. One-dimensional high resolution ^{1}H or ^{13}C spectra of lignin can be obtained directly or after acetylation. The acetylation can improve the resolution of spectra and provide as well information on the primary, secondary, and phenolic OH groups from the carbonyl signals of the corresponding esters. For a good signal-to-noise ratio extreme long measurement times are required for ^{13}C spectra [60]. Here the short measurement times of ^{1}H spectra are advantageously, although the information is more limited. Besides the methoxy signals, a differentiation of phenolic and aliphatic hydroxyl groups, and information on the protons in aromatic and various aliphatic structures can be obtained. As an alternative ^{31}P and ^{19}F NMR spectra can be recorded with good sensitivity and short measurement times after labeling reactions with P and F containing reagents. The resulting spectra cannot provide information on the entire lignin structure, but on different hydroxyl, aldehyde, keto and quinone groups [61, 62].

The large number of signals in the carbon and proton spectra results in an intense overlapping of signals. This can be resolved by heteronuclear single- and multiple-bond shift correlation spectra which provide 2D plots for proton and carbon shifts. Under normal operation conditions 2D spectra are not suitable for quantification. However, various approaches have been developed in the early 2000s in order to enable a quantitative determination of lignin either by a calibration of the 2D spectra [63] or by a remodeling of the pulse sequences [64]. Also 3D spectra of lignin have been recorded [65, 66].

6.4. Degradation Techniques

Many methods for the determination of intermonomer bonds of lignin are based on analytical degradation procedures. The degradation by alkaline solutions of potassium permanganate was used intensively by Freudenberg's group in the 1950s and 1960s and further modified by Miksche and coworkers. Accordingly different variations of the method exist and are reviewed in [61]. The protocol consists of several reaction steps and result in mono- and dimeric aromatic carboxylic methyl esters, which can be analyzed by gas chromatography. This shows not only the proportion of hydroxyphenyl, guaiacyl, and syringyl units but allow calculation of the abundance of different lignin substructures on a molar basis. The procedure is applicable to all kind of lignins but has the disadvantage of a rather complicated multi-step protocol which requires an elaborated data treatment in order to conclude on the original lignin structure [68].

The thioacidolysis of lignin encompasses mainly the cleavage of β-O-4 linkages with boron trifluoride etherate and ethanethiol in anhydrous media. The monomeric degradation products can be analyzed by gas chromatography and normally between 1000 to 3000 µmol/g

of mono- and dimeric degradation products are obtained. The protocol is accordingly simpler and allows an evaluation of the amount of alkyl-aryl ethers in lignin samples. A disadvantage is the strong odor of the reagents and the fact that the method is less informative on degraded samples, which is sometimes the case with some technical lignins [68, 69].

Derivatization followed by reductive cleavage (DFRC) was introduced as a new degradation method for lignin analysis [70]. Lignin is derivatized with acetyl bromide, followed by a reductive cleavage with zinc dust in a mixture of dioxane, acetic acid, and water (5:4:1). The resulting products are then acetylated and analyzed by gas chromatography. In the DFRC procedure hydroxyphenyl, guaiacyl, and syringyl units linked by α- and β-aryl ethers are cleaved and transferred into 4-acetocinnamyl acetate, coniferyl diacetate, and sinapyl diacetate.

The pyrolysis of lignin or lignocellulosic materials, i.e., the thermal degradation in the absence of oxygen, leads to the formation of a large variety of volatile components, which contain information on the original structure. In analytical pyrolysis this degradation technique is combined online or offline with other analytical techniques and most importantly with mass spectrometry (Py-MS) or gas chromatography and mass spectrometry Py-GC/MS. In the GC or GC/MS analysis of pyrolysis degradation products more than 100 peaks are found. Accordingly, the evaluation requires a large database and is based on statistical evaluation methods. Information on various pyrolysis techniques is found, e.g., in [71, 72]. A general review on MS techniques in combination with all relevant lignin degradation techniques can be found in [73].

6.5. Molar Mass Determination

Size-exclusion chromatography (SEC) is the most common method to determine molar masses of lignins. Frequently, lignins were acetylated followed by SEC in THF using columns based on polystyrene – divinylbenzene [74]. However, in various round robin tests carried out by the World Energy Association and the European network Eurolignin this approach resulted in a tremendous variation of the calculated molar masses [75, 76]. This problem might be partly due to aggregation phenomena and partly due to interaction with the column material. Furthermore, the acetylation is not suitable for lignins containing carbohydrate impurities and for lignosulfonates, the most important technical lignins. Lignosulfonate samples have been recently investigated using a complex mixture of water, DMSO, sodium phosphate buffer, and sodium dodecyl sulfate [40]. A universal eluent system applicable to all technical lignins is sodium hydroxide, however, the handling is not so easy because most commercial prepacked columns for HPSEC cannot withstand the high alkalinity [74]. Recently DMSO – water – lithium bromide and dimethylacetamide – lithium chloride were applied as eluents, showing a good agreement with alkaline SEC [23]. The determination of absolute molar masses by light scattering is complicated by the fluorescence of lignin, while viscosimetric methods suffer from the low overall viscosity of the samples. All methods are affected by the impurities of technical samples especially by carbohydrates and ash. Recently matrix-assisted laser desorption ionization/time of flight (MALDI/TOF) was applied to lignins after a fractionation of the samples on SEC columns in order to obtain fractions with narrow polydispersity [77].

7. Uses

Most applications of lignin and lignosulfonates are based on their dispersing, binding, complexing, and emulsion-stabilizing properties. About 50 % of all *lignosulfonates* produced worldwide are used for concrete mixtures, usually in the form of calcium or sodium salts. Addition of 0.1-0.3 % lignosulfonates to cement retards the setting or hydration of concrete. The second most important application is as a binder for animal feed pellets, where mainly calcium and ammonium salts are applied in order to improve pellet durability and abrasive resistance. A maximum dosage of 4 % is possible in finished pellets. Primarily chrome and ferrochrome salts of lignosulfonates function in oil well drilling muds as mud thinners, clay conditioners, viscosity-control agents, and fluid-loss additives. Mud

Table 4. Data on the toxicity of different lignosulfonates [38]

Property	Calcium lignosulfonate	Sodium lignosulfonate	Ammonium lignosulfonate
Acute toxicity LD_{50}, mg/kg	> 2 000	> 10 000	> 10 000
Eye irritant	no	no	no
Skin irritant	no	no	no
Fish toxicity LC_{50}, mg/L	> 1 000	> 1 000	> 1 000
Bacteria toxicity EC_{10}, mg/L	5 000	5 000	343

systems conditioned with 0.2–0.5 % lignosulfonates, applied in the crude oil industry, perform well at high pressures and at temperatures of up to 175 °C. Another major market, especially for crude lignosulfonate spent liquors, is the dust control application for stabilizing insurfaced roads. In addition to these bulk applications a variety of speciality markets exist. Lignosulfonates are used for the granulation, complexation, or encapsulation of pesticides and as additives for gypsum boards in order to disperse the stucco. Lignosulfonates are used as dispersant in water-based paints and inks. Lignosulfonates and spent sulfite liquors are used for water treatment plants and paper machines to reduce deposits and slime formation or to complex metals such as zinc in cooling-water cycles. They are used in industrial cleaner formulations, for the complexation of nutrients in soil stabilization, for dyes or as additives in the brick industry. Modified lignosulfonates are additives in lead–acid batteries, which extend the service life of the product significantly. As further future uses the stabilization of enzyme formulations, biocide neutralization, and applications exploiting the antiviral and the chelating properties have been targeted [38].

Borregaard LignoTech still produces vanillin from softwood lignosulfonates, while all other producers closed down their production due to lower costs for vanillin production from petrochemical feedstocks. This was also the reason for stopping the production of dimethyl sulfoxide (DMSO) from kraft lignin by heating black liquor with sulfur to above 200 °C to obtain dimethyl sulfide (DMS), which upon oxidation with dinitrogen tetroxide (N_2O_4) yielded DMSO [78].

Up to now, much work has been carried out on new utilizations of lignin (see for instance [79]). Only few applications are economically feasible, taking into account that lignin is currently burnt, covering not only the energy demand of the pulp mills but providing a significant surplus of energy. Sometimes the argument occurs that the utilization of lignin as a chemical feedstock will increase at higher oil prices. However, one has to keep in mind that the economic burning value of lignin is increasing as well when the overall energy costs are rising. Accordingly, the changes for implementing new applications are higher when lignin is used not as a bulk chemical but as a specialty product using its specific properties.

8. Toxicology

Lignosulfonates are considered as nontoxic at the typical use levels and they are approved, e.g., by the U.S. Food and Drug Administration for a variety of applications in food packaging and food production. Examples are the use as a boiler-water additive for the production of steam, which comes into contact with food (21 CFR 173.310), or the approval of calcium lignosulfonates as a "specific usage additive" for the regulations on food additives for direct addition to food for human consumption (21 CFR 172.172). Some data for various lignosulfonates are listed in Table 4 [38]. However, one should keep in mind that the properties of a specific product are not only influenced by its lignosulfonate component but by its impurities.

1. Introduction

Limestone is a naturally occurring mineral that consists principally of calcium carbonate but may also contain magnesium carbonate as a secondary component. It is found in many forms and is classified in terms of its origin, chemical composition, structure, and geological formation. Limestone occurs widely throughout the world and is an essential raw material for many industries.

Quicklime is produced by the thermal decomposition of limestone. It consists mainly of calcium oxide. Its quality depends on many factors, including physical properties, degree of sintering, and chemical composition. As the most readily available and cost effective alkaline chemical, quicklime plays an essential part in a wide variety of industrial processes.

Hydrated lime and slaked lime are produced by reacting quicklime with water; they consist mainly of calcium hydroxide. In general, hydrated lime refers to a dry calcium hydroxide powder, while slaked lime refers to an aqueous suspension of calcium hydroxide particles in water. Hydrated and slaked lime are widely used in aqueous systems as low-cost alkaline chemical.

The term lime refers to quicklime and, less frequently, to hydrated or slaked lime. It is, however, sometimes used incorrectly to describe limestone, which is a frequent cause of confusion.

History. Limestone was probably used in the Stone Age. The first records relate to the Egyptian Second Dynasty (ca. 2800 B.C.), when it was employed in the construction of the Giza Pyramids. Marble, a highly crystalline form of limestone, was used by the Greeks shortly after this period for statues and the decoration of buildings. Limestone was widely used by the Romans for building roads.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_317

There is evidence of the widespread use of quicklime and hydrated lime for building by many civilisations by about 1000 B.C., including the Greeks, Egyptians, Romans, Incas, Mayas, Chinese, and Mogul Indians. The Romans employed hydraulic lime in many construction projects, including the Appian Way.

Lime was also well known to the Romans as a chemical reagent. In 350 B.C. XENOPHON referred to the use of lime for bleaching linen. The medical use of limewater was recorded by DIOSCORIDES in 75 A.D.

The burning of limestone in kilns was mentioned by CATO in 184 B.C. PLINY THE ELDER (ca. 70 A.D), in his "Chapters on Chemical Subjects" described the production, slaking, and uses of lime, and stressed the importance of chemical purity.

The use of limestone and lime in building spread throughout Europe in the 1400s.

In the 1700s, JOSEPH BLACK gave the first sound technical explanation of the calcination of limestone, including the evolution of gaseous carbon dioxide. LAVOISIER confirmed and developed BLACK's explanation. In 1766, DE RAMECOURT, published a detailed account of "The Art of the Lime Burner" which covered the design, operation, and economic aspects of limestone quarrying and lime burning.

Terminology. Because the quarrying of limestone and the production of quicklime and hydrated lime are long-established industries, they have generated many traditional expressions which frequently cause confusion. The following definitions cover the most common terms. A more comprehensive list has been published [5].

Air limes consist maionly of calcium oxide or hydroxide, which, when incorporated into a mortar mix, slowly harden by reacting with atmospheric carbon dioxide.

Air-slaked lime is produced by excessive exposure of quicklime to the atmosphere. It contains varying proportions of the oxides, hydroxides, and carbonates of calcium and magnesium.

Agricultural lime is a term which includes any limestone, quicklime, or hydrated lime product used to neutralize soil acidity.

Aragonite is one of the less abundant crystalline forms of calcium carbonate.

Available lime is an analytical term for the calcium oxide content of quicklime or hydrated lime that is able to react with sucrose under specified conditions.

Bituminous limestone – see carbonaceous limestone.

Carbonaceous limestone contains organic matter as an impurity. It is often dark gray and has a musty odor.

Carboniferous limestone was deposited in the Carboniferous period, 286 to 360 million years ago.

Calcitic limestone refers to a high-calcium limestone.

Calcite is the most abundant crystalline form of calcium carbonate.

Cement is produced by calcining limestone with materials containing silica, alumina, and iron oxide to produce a controlled blend of calcium silicates, aluminates, and ferrates in the form of a clinker. The clinker is then ground with gypsum and other materials to form cement.

Chalk is a naturally occurring limestone, which has been partially consolidated and therefore has a high porosity. It is generally relatively soft.

Chemical quality limestone is a high-calcium or dolomitic limestone with low levels of impurities, which meets the requirements of the chemical industry.

Dead-burned dolomite is a highly sintered form of dolomitic quicklime which is used primarily as a basic refractory.

Dolime refers to calcined dolomite.

Dolomite is strictly speaking the double carbonate containing 54 – 58 % of $CaCO_3$ and 40 – 44 % of $MgCO_3$. The term is, however, frequently used to describe dolomitic limestone.

Dolomitic limestone is generally understood to contain 20 – 44 % of $MgCO_3$.

Fine quicklime generally refers to screened products with a top size below 0.6 cm.

Free lime is an analytical term for the calcium oxide component of quicklime or hydrated lime. It excludes calcium oxide in $CaCO_3$, $Ca(OH)_2$, and calcium silicates.

Granular quicklime usually refers to screened products with a top size of 0.5 – 2.5 cm.

Ground quicklime refers to powdered products produced by milling.

Hard-burned quicklime is a sintered form of quicklime with low reactivity to water.

High-calcium limestone is a general term for limestone consisting mainly of $CaCO_3$ and having a low content of $MgCO_3$ (max. 2 – 5 %). Similarly, high-calcium quicklime contains mainly CaO and not more than 2 – 5 % MgO.

Hydrated lime is a dry powder produced by reacting quicklime with controlled amounts of water.

Hydraulic limestone is an impure carbonate containing considerable amounts of silica and alumina. Calcination of hydraulic limestone produces *hydraulic lime*, which, after mixing with water, has cementing (or hydraulic) properties and is capable of setting under water.

Iceland spar is a rare and very pure form of crystalline limestone. It is transparent and has been used in optical instruments.

Light-burned quicklime is quicklime that is lightly sintered and has a high reactivity to water.

Lime putty is a viscous dispersion of calcium hydroxide in water.

Lump quicklime usually refers to screened products with a top size above 6 cm.

Magnesian limestone is generally understood to be mainly $CaCO_3$ with 5 – 20 % of $MgCO_3$.

Marble is a highly crystalline carbonate rock which may be high-calcium or dolomitic limestone. It occurs in many colors with veined and mottled effects.

Marl is an impure, soft, earthy rock which contains clay and sand. If it contains more than 50 % $CaCO_3$, it is classified as a limestone.

Milk of lime is a fluid suspension of hydrated or slaked lime in water.

Neutralizing value is an analytical term for that proportion of limestone, quicklime, or hydrated lime (expressed as CaO) that is capable of reacting with hydrochloric acid under specified conditions. It includes the contribution of $CaCO_3$, CaO, $Ca(OH)_2$, and the acid soluble fraction of the calcium silicates, aluminates, and ferrates.

Pebble quicklime usually refers to screened products with a top size of 1.5 – 6 cm.

Precipitated calcium carbonate (PCC) is produced by blowing carbon dioxide into milk of lime, thereby precipitating finely divided calcium carbonate with a mean particle size in the range 0.02 to 0.2 µm.

Reactivity of quicklime is a measure of the rate at which it reacts with water. There are many reactivity tests (see Section 3.1).

Slaked lime generally describes an aqueous suspension of mainly calcium hydroxide. It includes milk of lime and lime putties. The term slaked lime is sometimes used to describe hydrated lime.

Soft-burned quicklime – see light-burned quicklime.

Solid-burned quicklime – see hard-burned quicklime.

Total lime is an analytical term for the total CaO plus MgO content of a limestone or lime, expressed in terms of CaO equivalent. It includes the carbonates, oxides, hydroxides, silicates, aluminates, and ferrates.

Type N or normal hydrated lime is defined in ASTM specification C-207 [2]. It is generally produced by hydrating high-calcium quicklime at ca. 100 °C.

Type S hydrated lime is also defined in ASTM specification C-207 [2]. It is produced by heating high-calcium or magnesian lime in an autoclave at ca. 180 °C. It may contain up to 8 % of unhydrated oxide.

Whiting is a finely powdered product produced by milling and classifying limestone (generally chalk). The nominal top size varies from 75 to 10 µm.

2. Limestone

2.1. Physical and Chemical Properties

The physical and chemical properties of limestones vary widely as a result of the origin of the deposit, its microstructure, and impurities. The information given below is typical of most commercially exploited deposits.

Color. Pure calcite is white. Chalk and marble are also generally white, although impurities in the latter can produce a variety of colors and patterns. Many limestones, however, contain carbonaceous material, which produces various shades of gray. Iron compounds can introduce a red color. Some impurities produce a surface coloration on weathering.

Odor. Any odor possessed by limestone generally arises from its content of carbonaceous material. The smell is musty or earthy.

Structure. All limestones are crystalline. The grain size increases with the amount of recrystallization that has occurred during formation of the deposit. Thus, shell limestones have a grain size of ca. 1 µm, marls and chalks from 2 to 5 µm, dense limestones from 5 to 250 µm, and marbles and calcite spar from 250 to 1000 µm. Calcite and dolomite have rhombohedral crystal structures, and aragonite is orthorhombic.

Porosity. The porosity of limestone decreases with increasing levels of compaction. Thus, marls have up to 50 % porosity, chalks 15 – 40 %, dense limestones 0.1 – 10 %, and calcite spar <1 %.

Density. For pure calcite, the density is 2.71 g/cm^3 at 20 °C; for aragonite and dolomite, it is 2.93 g/cm^3 and 2.86 g/cm^3, respectively. The porosity of limestone results in apparent densities of 1.5 – 2.3 g/cm^3 for chalk, up to 2.7 g/cm^3 for high-calcium limestone, and 2.7 – 2.9 g/cm^3 for dolomitic limestones.

Bulk Density. The bulk density depends primarily on the apparent density of the limestone and its particle size distribution. Crushed, screened limestone with a 2 : 1 size ratio generally has a bulk density of 1300 – 1450 kg/m^3. Crushed limestone, including the fines, has a bulk density of 1600 – 1750 kg/m^3.

Impurities. Magnesium carbonate is not generally regarded as an impurity. Impurities may be dispersed homogeneously as a result of their being present during the deposition process. Alternatively they may be present heterogeneously in features such as faults, bedding planes, or nodules. Silica and alumina, in the form of clay, silt, and sand, are commonly found as homogeneous impurities, but also occur as heterogeneous impurities. Similarly, iron can exist homogeneously as iron carbonate and heterogeneously as pyrite and limonite. Sulfur from sulfates and organic remains generally exists as a homogeneous impurity. Other trace impurities such as lead are often found in the vicinity of faults where mineralization has occurred. Typical levels of trace elements are given in Table 1.

Table 1. Typical ranges of impurities and trace elements in commercial limestones

Impurity/trace element	Typical range	Units
Silica (as SiO_2)	0.1 – 2.0	%
Alumina (as Al_2O_3)	0.04 – 1.5	%
Iron (as Fe_2O_3)	0.02 – 0.6	%
Sulfur (as $CaSO_4$)	0.01 – 0.5	%
Carbonaceous matter	0.01 – 0.5	%
Manganese (as MnO_2)	20 – 1000	mg/kg
Antimony	0.1 – 3	mg/kg
Arsenic	0.1 – 15	mg/kg
Boron	1 – 20	mg/kg
Cadmium	0.1 – 1.5	mg/kg
Chromium	3 – 15	mg/kg
Copper	1 – 30	mg/kg
Fluoride	5 – 3000	mg/kg
Lead	0.5 – 30	mg/kg
Mercury	0.02 – 0.1	mg/kg
Molybdenum	0.1 – 4	mg/kg
Nickel	0.5 – 15	mg/kg
Selenium	0.02 – 3	mg/kg
Silver	0.2 – 4	mg/kg
Tin	0.1 – 15	mg/kg
Vanadium	1 – 20	mg/kg
Zinc	3 – 500	mg/kg

Hardness. Pure calcite has a hardness of 3 Mohs. Naturally occurring limestones lie in the range 2 – 4 Mohs.

Strength. The compressive strength of limestone varies from 10 MPa for some marls and chalks to 200 MPa for some marbles.

Specific Heat. The specific heats of high-calcium limestone and dolomite at 20 °C are 817 and 880 J kg^{-1}K^{-1}, respectively. They increase with temperature [3].

Solubility. The solubility of calcite in distilled water free of carbon dioxide has been reported as ca. 15 mg/L at 20 °C [1]. The solubility in distilled water in equilibrium with atmospheric carbon dioxide is approximately double the above value. Dolomite has been reported as being somewhat more soluble than calcite [1].

Reaction with Acids. Calcium carbonate reacts with acids with evolution of carbon dioxide and heat (reported to be about 19 kJ/mol in hydrochloric acid [4]).

pH. Both limestone and dolomite are essentially neutral products, giving pH values of 8.0 – 9.2.

Thermal Dissociation. The heat of dissociation of calcium carbonate is 3180 kJ/kg of CaO relative to 25 °C, and 3010 kJ/kg relative to 900 °C (760 kcal/kg and 720 kcal/kg, respectively). The corresponding values for magnesium carbonate are 3010 kJ/kg MgO relative to 25 °C, and 2850 kJ/kg relative to 700 °C.

2.2. Formation and Occurrence

Limestone is widely distributed throughout the world in deposits of varying sizes and degrees of purity. Information regarding the deposits in a given country is generally best obtained by contacting the appropriate national geological society.

The process of limestone formation is believed to have started with the extraction of calcium salts from the earliest forms of igneous rocks by the combined effects of erosion by the weather and corrosion by dissolved acids, e.g., sulfurous acid and carbon dioxide.

Under certain conditions of concentration and temperature, calcium carbonate precipitated from the solutions of calcium salts. Deposits with such chemical origins are generally thin, of limited extent, and therefore of little commercial importance.

When the solutions of calcium salts drained into the sea, marine life extracted the dissolved calcium hydrogen carbonate component to build shells and skeletons of calcium carbonate. These gradually accumulated on the beds of shallow tropical seas to produce deposits, many of which were massive. The calcium carbonate became contaminated by waterborne clays and silts, and by airborne volcanic ash. The extent of contamination dependent on the distance from estuaries and volcanoes. In general the purest deposits originated from mid-ocean banks remote from land.

The limestone deposits became covered with other materials and were subjected to solvent action under high pressure and temperature. This consolidated the deposits and caused recrystallization to varying degrees. The sequence marl, chalk, limestone, and marble shows progressive consolidation and change of structure. Soft marls are porous and contain well-defined fossils. Marble is particularly dense, highly crystalline, and contains no discernible fossils. The grain size ranges from less than 5 µm for marls to over 250 µm for some marbles and calcite. The process of recrystallization is known as metamorphosis.

Under certain conditions, magnesium ions present in the seawater replaced alternate calcium ions in the calcite to form dolomite. This process is known as dolomitization.

2.3. Production

Most limestone is produced by open-cast quarrying. A small proportion (less than 5 %) is extracted by underground mining and a still smaller proportion (less than 1 %) as cut dimension-stone.

The first operation in open-cast quarrying is to remove the overburden (i.e., the soil, clay, and rock overlying the deposit). Various techniques and types of earth moving equipment are used for this.

The next stage is generally to drill the bedrock. Rotary and percussive drills are widely used to drill the holes. The spacing between holes and the burden (distance between the holes and the quarry face) is carefully controlled. The diameter of the holes varies from 5 – 25 cm, depending on the design of the blast.

The drill holes are then filled with controlled amounts of explosive. A mixture of ammonium nitrate and fuel oil (ANFO) is widely used; it is initiated with a high explosive. In a typical blast, 5000 – 50 000 t of stone is fragmented with about 140 g of explosive per 1 t limestone.

It is important to control the blast. Too little fragmentation produces oversize boulders which have to be broken using secondary blasting or a drop ball. Too much fragmentation produces an excessive amount of fine particles and increases the risk of throwing rock away from the quarry face. Optimum fragmentation is obtained by selection of the correct diameter and spacing of holes, time delay between holes, thickness of burden, and quantity of explosive.

Some soft rocks, e.g., chalk and marl, are broken by using heavy rippers. Other soft deposits,

as found in lakes or in the sea, are extracted with dredgers. Underground mining is used when the overburden is thick, or when the limestone deposit is overlain by other rocks. Most mines use the room and pillar technique. After blasting, the rock is loaded into dump trucks, generally by front-end shovels or hydraulic excavators and transported to the crushing and screening plant. In the crushing and screening plant, the larger lumps of rock are broken in a primary crusher to a size which suits the needs of the business and the characteristics of subsequent equipment. The rock is then screened into oversize (e.g., + 15 cm), large (e.g., − 15 + 5 cm), medium (e.g., − 5 + 0.6 cm), and fine (e.g., − 0.6 cm) fractions. The oversize stone is frequently recrushed and rescreened. The fine fraction is rich in impurities such as clay, and is often tipped. In some plants clay and the fine fractions are removed more efficiently by washing and screening.

Compression machines such as jaw, gyratory, and rolls crushers are generally selected when the amount of fine fraction must be minimized and when slabby lumps can be tolerated. Impact crushers such as hammer mills and impact breakers are selected when cubical lumps are required and increased fines production can be tolerated. Impact crushers have the advantage of being able to achieve a greater size reduction at lower capital cost. Although the major demand for limestone is in the − 2.5 + 0.1 cm size range, specialized requirements exist for very finely divided products, which are produced in a variety of mills, generally by dry grinding.

Dimension-stone production (for facing buildings and ornamental use) is a specialized process in which blocks are cut from the rock face with channelling machines or wire saws. The blocks are then cut, shaped, and, if required, polished to make the finished product.

2.4. Uses and Specifications

Construction. Limestone is the most widely used crushed rock, although it is generally outsold by sand and gravel.

The quality specifications for construction stone relate mainly to its physical properties. Thus the stone must be clean, strong, dense, durable, free from cracks, and have the required particle size distribution. Some specifications limit the amounts of organic matter, clay, or water-soluble components (e.g., alkali-metal salts and gypsum). Specifications for the stone in the top dressing of roads (particularly in the vicinity of junctions) sometimes require a high resistance to polishing; this excludes the use of limestone. Standards for the testing and size distribution of roadstone and construction stone are given in Section 6.2.

Cement. The production of cement is the main use for chalk, and a major use for dense, high-calcium limestone. Approximately 1.0 t of limestone is required for 1 t cement. For the estimated worldwide production of cement in 1994, the consumption of limestone was ca. 1420×10^6 t [5].

Because cement is a mixture of calcium silicates, aluminate, and ferrate, the presence of SiO_2, Al_2O_3, and Fe_2O_3 in the feedstone is acceptable, provided the level is uniform. When the composition of the limestone is variable, elaborate arrangements are made to produce a consistent chemical analysis by blending. The magnesium carbonate content, however, must be below 5 %. For further details of cement production, see → Cement and Concrete.

Quicklime. Approximately 1.8 t of limestone is required per 1.0 t of quicklime. Further details are given in Section 3.2.

Agriculture. Many crops grow best under neutral to slightly acid conditions (i.e., pH 6 – 7). Thus soils which are more acidic than pH 6 generally benefit from the application of limestone. The limestone also helps to replace the calcium and magnesium removed by crops. Other benefits include an increase in the supply of other chemical nutrients, an increase in the organic matter of the soil, an increase in beneficial soil microorganisms, improved soil tilth, an improved supply of trace elements, and an increase in the efficiency with which fertilizers are used by the crop [5].

It is important that the limestone used for agriculture is in the correct physical state; a top size of ca. 0.3 cm is generally required. The delivered cost per tonne of carbonate is an important factor. In some cases, the magnesium con-

tent of dolomite gives it an advantage over high calcium limestone.

Limestone is also used in animal feeds and poultry grit. In animal feeds, trace elements may be restricted (e.g., lead levels below 10 mg/kg).

Metal Refining. When limestone is used in metal refining it is initially converted to quicklime, which reacts with acidic oxides (e.g., SiO_2, Al_2O_3, and Fe_2O_3) to produce molten slags. Most is used in blast furnaces for the production of iron, where the slag typically contains 40–50 % CaO. Smaller amounts are used in the production of copper, lead, zinc, and antimony. The quality requirements are as for chemical-quality stone. Some magnesium carbonate is acceptable but not essential.

Flue Gas Desulfurization. A growing use of limestone is in the treatment of flue gas to remove sulfur dioxide. For the wet scrubbing process the limestone is finely ground to 90 % less than 45 µm and contacted with flue gases in a scrubber. The resulting calcium sulfate may be converted to salable gypsum, in which case the $MgCO_3$ content should not exceed 1 %. In the dry process finely divided limestone is injected into the furnace, where it is converted to quicklime, which then reacts with the sulfur dioxide.

Other Uses. There are many other uses of limestone, e.g., production of alumina, glass, wood pulp, paper, ceramics, mineral wool, fillers, whiting, and coal-mine dusts, neutralization of acids and construction of filter beds; they are described in [5].

3. Quicklime

3.1. Physical and Chemical Properties

Color. Most quicklimes are white. Impurities can result in gray, brown, or yellow tints. When quicklime is produced by solid fuel firing, a gray surface contamination is produced.

Odor. Quicklime has a slight earthy odor.

Porosity. The porosity of commercially produced quicklime can be as high as 55 %, if a highly porous limestone is lightly burned. Exposure to elevated temperature results in sintering (see Fig. 1) which can reduce the porosity to below 25 %. Dead-burned dolomite has a porosity of ca. 10 %.

Figure 1. Scanning electron micrographs of quicklimes A) Apparent density 1.5 g/cm^3; B) Apparent density 1.9 g/cm^3; C) Apparent density 2.3 g/cm^3

Density. The true density of calcium oxide is ca. 3.3 g/cm^3. The apparent density of lumps can be as low as 1.4 g/cm^3 for highly porous quicklime. This can rise to over 2.3 g/cm^3 after sintering (Fig. 2).

Calcined dolomite is generally denser than high-calcium quicklime, if given the same heat treatment. Dead-burned dolomite has an apparent density of ca. 3.2 g/cm^3.

Bulk Density. The bulk density depends on the mean apparent density of the particles and on the voidage between them. The latter is related to the particle size distribution and the particle shape. Most screened commercial quicklime products have compacted bulk densities of 900–1200 kg/m^3. Inclusion of fines can increase the bulk density by 30 %.

Figure 2. Variation of apparent density with temperature and time for a dense, high-calcium quicklime
a) At 1400 °C; b) 1300 °C; c) 1200 °C; d) 1100 °C; e) 1000 °C

Hardness. Most commercial quicklime products have a hardness of 2 – 3 Mohs. The value for dead-burned dolomite is in the range 3 to 5 Mohs.

Melting Point. The melting points for calcium oxide and magnesium oxide are 2580 °C and 2800 °C, respectively. The value for calcined dolomite is about 2400 °C [1].

Specific Heat. The mean specific heats for high-calcium and dolomitic quicklime at 20 °C are 760 and 830 J kg^{-1} K^{-1}, respectively. They increase with temperature [3].

Angle of Repose. The angle of repose for cubical, well-graded pebble quicklime is about 35°. This increases, however, as the fines content increases. For bunker design, valley angles of not less than 60 ° are recommended.

Heat of Hydration. The heat liberated by the reaction of quicklime with water is 1140 kJ/kg of CaO. The value for dolime is 880 kJ/kg of CaO · MgO.

Figure 3. Comparisons between reactivity tests for a high-calcium quicklime
a) BS 6463 1987, °C after 2 min [7]; b) EN 459-2, t_{60} (min.) – time to reach 60 °C [8]; c) EN 459-2, t_u (min.) – time for 80 % slaking [8]; d) ASTM C 110, temperature rise (°C) after 30 sec [9]; e) ASTM C 110, maximum temperature rise (°C) [9]; f) ASTM C 110, time to maximum temperature (min.) [9]; g) Acid titration, (mL) at 3 min [10]; h) Acid titration, (mL) at 5 min [10]; i) Acid titration, (mL) at 10 min [10]

Reactivity to water may be measured by the rate of release of the heat of hydration [7–9] or by the rate at which an aqueous suspension reacts with hydrochloric acid [10]. The relationships between some reactivity tests are are shown in Figure 3. Reactivity is also related to the mean apparent density of quicklime produced from a given source stone (Fig. 4).

Figure 4. Relationship between reactivity and apparent density for a high-calcium quicklime

It should be noted that the reactivity of quicklime can be markedly affected by impurities in the water. For this reason, distilled water should be used as a reference standard.

The low reactivity of calcined dolomite probably arises mainly from the low solubility of $Mg(OH)_2$ in water. Sintering of MgO, which forms at lower temperatures than CaO may also be a factor.

Affinity for Water. Quicklime has a high affinity for water and is a more efficient desiccant than silica gel. Because of its high affinity for water vapor and (after partial hydration) for carbon dioxide, care should be taken to minimize exposure of quicklime to the atmosphere. Relatively small amounts of air slaking (less than 1.5 % of combined water) can reduce the reactivity significantly.

The reaction of quicklime with water is associated with an increase in volume by a factor of at least 2.5. This can cause the expansion of products that contain some lime which is not fully hydrated.

Reaction with Carbon Dioxide. In the absence of calcium hydroxide, quicklime only reacts with dry carbon dioxide above ca. 300 °C and below ca. 800 °C, depending on the carbon dioxide pressure. Partial recarbonation in the absence of calcium hydroxide can occur in lime kilns under certain abnormal conditions. It can produce an unexpectedly low reactivity and markedly affects the normal relationship between reactivity and mean apparent specific gravity.

Acid Neutralization. Quicklime is used extensively to neutralize acidic oxides, such as SiO_2, Al_2O_3, and Fe_2O_3, in high-temperature nonaqueous systems (e.g., in steel making). Temperatures are generally controlled to ensure that the resulting calcium and magnesium salts produce molten slags.

Reaction with Carbon. Above 1800 °C, carbon reduces calcium oxide to produce calcium carbide and carbon monoxide.

3.2. Raw Materials

3.2.1. Limestone

Size. The ratio of the top to bottom sizes in the stone fed to lime kilns should preferably be 2 : 1 and certainly no more than 3 : 1. This gives an open, porous bed which offers a low resistance to gas flow and heat transfer. The narrow size range also helps to limit sintering of the smaller sizes while the larger are still dissociating. Selection of the size is influenced by the cost and availability of the stone and by the limitations imposed by the design of the lime kiln.

Shape. While a cubical shape is generally preferred for lime kilns, the slabby shapes produced by jaw and roll crushers are acceptable, providing they do not lead to a packed bed with low porosity.

Strength and Abrasion Resistance. Both the stone and the quicklime should be sufficiently strong to resist the physical forces to which they are exposed in the kiln and the handling and storage system. Excessive breakage

in the kiln increases the resistance to gas flow and heat transfer. Breakage reduces the yield of granular products, which are usually at a premium, and increases the yield of fines, which are usually in surplus. Various empirical tests have been developed by kiln manufacturers to quantify the above factors.

Thermal Degradation. Some limestones, and particularly highly crystalline ones, are prone to break-down as a result of the heating, calcining, or thermal cycling processes within the kiln. Various empirical tests have been developed to quantify these effects.

Water. Some chalks are highly porous and may contain 20 % water, which reduces the temperature of the kiln exhaust gas and may cause condensation problems in dust collectors.

Impurities. When limestone is burned in a kiln, most of the impurities persist in the quicklime. Permissible levels of SiO_2, MgO, Al_2O_3, Fe_2O_3, S, Pb, and F depend on the quality specifications for the quicklime. Heterogeneous impurities (e.g., those arising from contamination with clay) tend to concentrate in the smaller sizes of quicklime. Removal of the fines (e.g., − 6 mm) by screening generally improves product quality. Much of the sodium and potassium compounds and some of the sulfur compounds are removed during calcination. Sulfur oxides, most of which may arise from the fuel, and volatile impurities, such as Pb and F, are reabsorbed onto the surface of the quicklime at the start of the calcining zone and concentrate in the fine fraction.

3.2.2. Fuel

In lime burning, the fuel is more than a source of heat. It interacts with the process, and the combustion products react with the quicklime. Many different fuels are used in lime kilns. The most common is coal. Coke, fuel oil, and natural gas are also widely used.

Selection of the correct fuel is important to the lime producer. Its cost per tonne of quicklime frequently represents 50 % of the total production cost. Some fuels cannot be used in certain kilns. Other fuels may markedly affect the heat usage, output, and product quality. Some require different refractory linings to be used.

The selection of a new fuel, e.g., a different coal, is often a matter of trial and error. The selection for a new kiln should be made with great care. Most kilns can be operated on more than one fuel, and this enables the operator to select the fuel or combination of fuels which gives the optimum economic performance.

The major factors relating to the performance and acceptability of fuel are discussed briefly below. Further details are available in [5].

Calorific Value. The calorific value coupled with the unit cost of the fuel and the kiln heat usage enables the cost of the fuel per unit of quicklime to be calculated. Some confusion arises between the gross (or upper) and the net (or lower) calorific values. The former includes the latent heat of condensation of the water produced by combustion; it is used in North America and the United Kingdom. The net value more logically excludes the latent heat; it is widely used in, for example, continental Europe and Japan.

Sulfur. Some important markets for quicklime, notably steelmaking, require low sulfur levels. Sulfur from the fuel is absorbed by quicklime in the cooler part of the calcining zone of lime kilns as calcium sulfate. In the more efficient kilns, e.g., shaft kilns, most of this sulfur is retained in the quicklime. In the less efficient units, e.g., some rotary kilns, much of the sulfur from the fuel may be eliminated from the kiln in the kiln gases by operating the calcining zone with low levels of excess air and high temperatures, and by limiting contact between the kiln gases and the quicklime in the cooler part of that zone.

Combustion Characteristics. The combustion characteristics of fuels vary markedly. Pulverized coal tends to burn with a short, hot, and highly (infrared) emissive flame. Natural gas and wood burn with longer, cooler flames which have lower emissivities. These differences can affect heat usage and many aspects of quality. In particular the relationship between the residual $CaCO_3$ content and the reactivity to water may be affected by the choice of fuel.

Particle Size. Solid fuels should be of the correct particle size. In some cases they need to have adequate strength. Their coking properties may be critical, as may be the amount of volatile matter. The ash generally contaminates the lime to some degree with silica, iron oxide, and alumina. It may cause bridging between particles, and can also combine with lime dust and with volatile alkalis (sodium and potassium) to form troublesome deposits.

Ash Fusion. The properties of the fuel ash can have a marked effect on the acceptability of the fuel. Key properties include the ash content of the fuel, the ash fusion temperature (which is affected by lime dust and by the concentration of oxygen and carbon monoxide in the atmosphere), and the level of alkalis.

Figure 5. Variation of the CO_2 partial pressure above $CaCO_3$ with temperature

3.3. Production

3.3.1. Calcination

The chemical reaction for the decomposition of calcium carbonate by heat is:

$$CaCO_3 \longrightarrow CaO + CO_2$$

$$\Delta H = +3010\,\text{kJ/kg at } 900\,^\circ\text{C } (720\,\text{kcal/kg})$$

Figure 5 shows the variation of the partial pressure of carbon dioxide above calcium carbonate with temperature. The pressure is 101 kPa at ca. 900 °C. Thus, although surface calcination can proceed at lower temperatures, complete calcination only occurs above 900 °C.

The calcination mechanism is complex and involves several stages: heat transfer to the surface of the particle and through the outer layer of lime. The heat is absorbed by the chemical reaction at the lime – limestone interface. The carbon dioxide so generated migrates to the surface of the particle counter to the heat flow and then diffuses from the surface into the kiln gases.

Figure 6. Calcining times for spheres of a dense, high-calcium limestone
a) 15 cm; b) 12.5 cm; c) 10 cm; d) 7.5 cm; e) 5 cm; f) 2.5 cm diameter

The rate-determining stage in the above process depends on the particle size, temperature, amount of calcination that has already taken place, and the composition of the kiln gases. Although attempts have been made to produce a mathematical model to account for observed effects in practical lime burning, none has proved applicable over wide ranges of the above variables.

Figures 6 and 7 summarize smoothed results for calcining spheres of UK carboniferous limestone. Although the results do not apply accurately to the random shapes encountered in practice or to other limestones, they serve as a useful guide to the relative effect of changing residence time or temperature.

Figure 7. Progression of calcination of limestone spheres

Figure 6 shows the marked variation in the time for complete calcination caused by changes in particle size. This is one of the reasons why the size range of stone fed to lime kilns is generally in the ratio of 2 : 1. The other reasons are the effects on sintering and on the porosity of the stone bed, which must be sufficiently high to allow rapid gas flow and efficient heat transfer.

When a high-calcium limestone particle is decomposed at low temperature (950 °C or below), its external dimensions do not change significantly. Calcination of limestone with 2 % porosity theoretically produces quicklime with a porosity of 54 %, corresponding to an apparent density of 1.5 g/cm^3.

Prolonged heating of quicklime above 900 °C causes sintering, a reduction in porosity, and an increase in apparent density (see Fig. 2). This sintering process markedly reduces the reactivity of the quicklime to water (see Fig. 4).

In lime kilns, variations in heat distribution, temperature, and solids residence time further complicate the calcination process. As a result the quicklime particles discharged from the kiln can be grouped into three categories:

1) Particles that are not fully calcined (i.e., with a central $CaCO_3$ core), the lime layer of which has a low apparent density and a high reactivity to water
2) Particles that are just fully calcined and have a low apparent density and a high reactivity to water
3) Particles that have sintered to varying degrees and which have an increased apparent density and a reduced reactivity to water

The relative quantities of product in the above categories are influenced by the kiln design. In most kilns, the quicklime is exposed to gas temperatures of 1200 – 1300 °C just before it enters the cooling zone. Generally, such kilns only produce highly reactive quicklime from high-calcium limestone if the residual $CaCO_3$ content is relatively high. Some designs complete the calcination at a lower temperature (ca. 1100 °C), and produce a highly reactive quicklime with low levels of $CaCO_3$. In some kilns, changing the air – fuel ratio can affect the characteristics of the quicklime. A low ratio lengthens the flame, and hence the calcining zone, and reduces maximum gas temperatures. This leads to a higher reactivity for a given $CaCO_3$ content. It may, however, increase specific heat usage.

If the quicklime is exposed to kiln gases containing carbon dioxide at 600 – 800 °C, recarbonation occurs. This increases the $CaCO_3$ level and reduces the available lime content slightly. The most marked effect, however, is the reduction in the reactivity of the quicklime.

A small amount of recarbonation always occurs in the cooling zone of the kiln as a result of air slaking. The quantities involved are, however, small and the effect on the quality of the quicklime is negligible.

Any magnesium carbonate in the limestone decomposes at ca. 700 °C. Its heat of calcination is lower than that of calcium carbonate. The resulting magnesium oxide does not contribute significantly to the reactivity towards water.

3.3.2. Lime Kilns

Early lime kilns were constructed of stone and were generally built into the side of a hill [11]. An amount of fuel, originally wood, was placed on a hearth at the base of the kiln. Large stones

were placed above the fuel, followed by layers of increasingly smaller stone. The fuel was then lit and allowed to burn for a few days. After the fire had burned out and the lime had cooled, the kiln was drawn-down by hand from the hearth. The product often contained substantial amounts of both over- and under-burned lumps, and the thermal efficiencies were very low.

It was then recognized that a continuously operating lime kiln would be more productive and more thermally efficient. For the purpose of heat transfer, a kiln should be regarded as consisting of three zones (see Fig. 8).

Figure 8. Schematic of a vertical shaft kiln.
a) Preheating zone; b) Calcining zone; c) Cooling zone

In the pre-heating zone, limestone is heated from ambient temperature to over 800 °C by the heat of the gases emerging from the calcining zone. In the calcining zone, the calcium carbonate is decomposed into calcium oxide, thereby absorbing some of the heat of combustion produced by burning the fuel and preheated air. In the cooling zone, quicklime is cooled by part or all of the combustion air, which in turn is preheated.

Subsequently, vertical shaft, mixed-feed kilns were developed in which either layers of stone were alternated with layers of fuel (initially wood or coal) or a blend of stone and fuel was charged to the top of the kiln. Calcined quicklime was drawn from the base of the kiln and additional fuel and stone were charged into the top of the kiln. The thermal efficiencies of these designs were better than those of the earlier kilns, but were still poor, owing to the incomplete combustion of the volatile matter. Use of coke overcame this problem and high thermal efficiencies were obtained. A large number of shaft kiln designs were developed [11]. Kiln outputs were often increased by the use of fans to increase the air and exhaust gas flow rates.

Most of the kilns in current use are based on either the vertical shaft or on the rotary design. There are a few other kilns based on different principles. All of these designs incorporate the concept of the three zones. In some kilns, they are incorporated into one unit, in others they exist as separate units (see Fig. 13).

Vertical Shaft Designs. Figure 8 shows a schematic of a vertical shaft kiln. The major problem with shaft kilns is obtaining uniform heat release across the shaft. Fuel injected at a wall usually does not penetrate more than 1 m into a packed bed. This limits the kiln width (or diameter) to 2 m. Increased fuel penetration can be achieved in larger shafts by:

1) Use of the mixed feed technique,
2) Use of central burners or lances,
3) Injecting the fuel via tuyères which penetrate ca. 1 m into the kiln,
4) Injection of the fuel underneath arches, or
5) Injection of air or recycled kiln gas above the fuel.

In general, vertical shaft kilns have relatively low specific heat usages because of efficient heat transfer between the gases and the packed bed. However, they retain most of the sulfur in the fuel so that low-sulfur quicklime can only be produced if a low-sulfur (and generally expensive) fuel is used to calcine a low-sulfur stone.

Older designs tend to produce quicklime with a low to moderate reactivity and a relatively high $CaCO_3$ content. Modern designs incorporate features which enable highly reactive lime to be produced with low $CaCO_3$ levels. Five designs of shaft kiln, which are used extensively throughout the world, are described below.

Mixed-Feed Shaft Kiln. Modern mixed-feed kilns use limestone with a top size in the range 5 to 15 cm and a size ratio of ca. 2 : 1. The most widely used fuel is a dense grade of coke with low reactivity and low ash content. The coke size is only slightly smaller than that of the stone so that it moves with it rather than trickling through the interstices. The stone and coke are mixed together and are charged into the kiln in such a way as to minimize segregation.

The net heat usage can be very low at ca. 4000 kJ/kg (950 kcal/kg). This advantage is offset by the high cost of coke compared to competitive fuels. Another advantage of the mixed-feed shaft kiln is that it produces kiln gas with a very high CO_2 content. For processes which can use both the quicklime and the CO_2 (e.g., the precipitated calcium carbonate process, the Solvay process, and the sugar beet process), this is an important factor in the overall economics.

The quality of the quicklime tends to be moderate, with the reactivity being considerably lower than that obtained by rotary kilns at the same $CaCO_3$ level. This, however, can be an advantage for certain uses. The retention of sulfur from the fuel is high.

Double-Inclined Shaft Kiln. The double-inclined shaft kiln (Fig. 9) is essentially rectangular in cross section but incorporates two inclined sections in the calcining zone. Opposite each inclined section, offset arches create spaces into which fuel and preheated combustion air are fired via three combustion chambers. Cooling air is drawn into the base of the kiln and is preheated. Part of the air is withdrawn and re-injected via the combustion chambers. The tortuous paths for both the gases and the burden, coupled with firing from both sides, ensures efficient distribution of heat. These kilns accept stone with a top size of 4 to 10 cm. They can produce reactive, low-carbonate quicklime at a net heat usage of about 4300 kJ/kg (1030 kcal/kg). A range of solid, liquid and gaseous fuels can be used, although they should be selected with care to avoid excessive buildups caused by fuel ash and calcium sulfate deposits.

Figure 9. Schematic of a double-inclined shaft kiln
a) Upper burners; b) Lower burners

Multichamber Shaft Kiln. The multichamber shaft kiln is a development of the double-inclined kiln. It consists of four or six alternately inclined sections in the calcining zone, opposite each of which is an offset arch. The arches serve the same purpose as in the double-inclined shaft kiln. Cooling air is preheated by lime in the cooling zone, and is withdrawn, dedusted and re-injected via the combustion chambers. The temperature of the lower combustion chambers can be varied to control the reactivity of the quicklime over a wide range. The kiln can be fired with solid, liquid, and gaseous fuels

or a mixture thereof. Its net heat usage is about 4300 kJ/kg (1030 kcal/kg).

Figure 10. Schematic of an annular shaft kiln
a) Upper burners; b) Lower burners; c) Combustion air to upper burners; d) Combustion air to lower burners; e) Kiln gases

Annular Shaft Kiln. The major feature of the annular shaft kiln (Fig. 10) is a central cylinder which restricts the width of the annulus, and ensures good heat distribution. The central column also enables part of the combustion gases from the lower burners to be drawn down the shaft and to be injected back into the lower burner chamber. This recycle moderates the temperature at the lower burners and ensures that the final stages of calcination occur at low temperature. Both effects help to manufacture a product with a low $CaCO_3$ level and high reactivity.

The annular shaft kiln accepts stone with a top size of 5 – 11 cm. Use of a heat recuperator, in which 30 % of the kiln gases are used to preheat part of the combustion air, reduces the net heat usage to about 4180 kJ/kg (1000 kcal/kg). The kiln can be fired by gas, oil, or solid fuel.

Figure 11. Schematic of a parallel-flow regenerative kiln a) Fuel; b) Combustion air; c) Cooling air; d) Lances; e) Cross-duct; f) Shaft 1; g) Shaft 2

Parallel-Flow Regenerative Kiln. The parallel-flow regenerative kiln (Figs. 11 and 12) consists of two or three interconnected vertical shafts. The following description relates to the more common two-shafted design. The operation consists of two equal stages, each of which lasts about 10 min.

Figure 12. Two 300 t/d parallel-flow regenerative kilns

In the first stage, fuel is injected through lances into shaft 1 and burns with combustion air blown down the shaft. The heat released is partly absorbed by calcining the limestone in shaft 1. Air is blown into the base of each shaft to cool the lime. The air in shaft 1 mixes with the combustion gases, including the carbon dioxide from calcination. The mixture passes through the cross-duct into shaft 2, at about 1050 °C. In shaft 2, the gases from shaft 1 mix with the cooling air blown into shaft 2 and pass upwards. In so doing, they heat the stone in the pre-heating zone of that shaft.

During the second stage of the operation, the converse applies. The same amounts of fuel and combustion air are added to shaft 2. The combustion gases plus cooling air pass upwards in shaft 1, heating the stone in the pre-heating zone of that shaft.

The two key principles of the above operation are:

1) The stone-packed preheating zone in each shaft acts as a regenerative heat exchanger in addition to pre-heating the stone to calcining temperature. The surplus heat in the gases is transferred to the stone in shaft 2 during the first stage. It is then transferred from the stone to the combustion air in the second stage. As a result, the combustion air is preheated to about 800 °C. The net heat usage of the kiln is about 3770 kJ/kg (900 kcal/kg) of quicklime.
2) The calcination of the quicklime is completed at the level of the cross-duct at a moderate temperature of about 1100 °C. This favors the production of a highly reactive quicklime, which may, if required, be produced with a low $CaCO_3$ content. The kiln accepts stone with a top size of 5 – 12 cm, and it can be fired with gas, oil, or solid fuel.

Rotary Kilns. There are many designs and variants of the rotary kiln (Fig. 13). Most use a feedstone with a top size in the range 1 to 6 cm. They operate well on gaseous, liquid, or solid fuels.

Heat usages for rotary kilns are generally much higher than those of shaft kilns and their capital costs tend to be higher. These adverse factors are often offset by their ability to produce a high-quality quicklime with lower $CaCO_3$ and sulfur levels and high reactivity, when fired by less expensive fuels.

In the earliest rotary kilns, stone was charged into the elevated end of the rotating section (generally inclined at between 1.5 and 4°). It was preheated by the gases drawn from the calcining zone at the other end of the kiln, and then calcined as it moved towards and under the flame. The hot lime was then discharged into a pit to cool.

In later designs, the thermal efficiency of the rotary kiln is improved by:

1) Fitting lime coolers which preheat the combustion air,
2) Fitting raised sections of refractory (i.e., dams or mixers) in the calcining zone to improve heat transfer,

Figure 13. Schematic of a rotary kiln a) Burner; b) Combustion air; c) Pre-heater; d) Kiln; e) Cooler

3) Installing refractory trefoils, metal lifters, or similar devices in the pre-heating zone of the rotating section, or
4) Using a stone pre-heater, followed by a shorter rotary section.

Net heat usages of rotary kilns range from over 8370 kJ/kg (2000 kcal/kg) for the simplest gas-fired units, to about 5020 kJ/kg (1200 kcal/kg) for the more complex coal-fired installations.

One complication often associated with rotary kilns is the buildup of "rings" on the refractory material in the rotary section. They are produced by the combination of lime dust with clay, ash (if present), and sodium and potassium salts. They can be particularly troublesome in kilns fitted with preheaters and in coal-fired kilns. In the latter case, fine grinding of a well selected coal generally minimizes ring formation.

A particular advantage of rotary kilns without preheaters is that it is possible to eliminate most of the sulfur introduced with the fuel. This enables low-sulfur lime to be made with cheaper, high-sulfur fuels, subject to any limitations on sulfur dioxide emissions (see Section 5.4). Use of a preheater increases the contact between the combustion gases and the partially calcined stone, increases the absorption of sulfur dioxide, and reduces the ability to eliminate sulfur. Calcium sulfate deposits in the preheater can be troublesome.

Many lime producers have found that rotary kilns complement shaft kilns, because they use a smaller feedstone and produce quicklimes with different characteristics, which meet the requirements of certain customers.

Other Kilns. Many other designs of lime kiln have been developed, but few have gained wide acceptance. Recent noteworthy developments include the travelling grate (or CID) kiln and the top-shaped (or Chisaki) kiln, which accept limestone in the size ranges 1.5 – 4.5 cm and 0.5 – 4 cm, respectively [5]. A number of designs have been developed to calcine finely divided limestone. These include rotary kilns with suspension preheaters, flash calciners (to which a rotary kiln may be linked to facilitate control of the lime reactivity), and fluidized-bed kilns [5].

Dolime Kilns. Calcined dolomite is produced in both shaft and rotary kilns. Four qualities of calcined dolomite are produced: half-, light-, hard- and dead-burned. Half-burned dolomite ($CaCO_3 \cdot MgO$) is produced in small quantities in Germany using (it is believed) rotary kilns. Light-burned dolomite is produced in both rotary and shaft kilns. Hard-burned dolomite is generally produced in mixed-feed shaft kilns operating under reducing conditions. Two grades of dead-burned dolomite are produced. The high-purity grade, used for the manufacture of refractories, can be produced by direct

calcination of dolomite at up to 1800 °C in rotary or shaft kilns or by sintering pelletized, calcined dolomite at about 1800 °C, generally in rotary kilns. Fettling grade dolime is produced by heating a blend of finely divided calcined dolomite and iron oxide in a rotary kiln at 1400 – 1600 °C.

3.3.3. Quicklime Processing

The major demand is for the screened grades of quicklime in the range 4 to 0.6 cm. To obtain the maximum yield of those sizes, particularly from shaft kilns, it is generally necessary to crush the lime. Rolls and jaw crushers are often used because they minimize formation of fines. Surplus grades (generally − 0.6 cm) are often used as feed for the production of hydrated lime (see Chap. 4) or ground quicklime.

The production of finely ground quicklime has expanded markedly in recent years. As various grades are required, ranging from 30 to over 99 % passing 75 µm, they are generally produced in mills fitted with a variable speed classifier which returns coarse particles to the mill and controls the fineness of the finished product.

3.4. Uses and Specifications

Iron and Steel. A small amount of lime is used in the production of iron ore agglomerates from fines. The main advantage of adding 1 – 2 % of quicklime to the ore is a marked increase in the production capacity of the sinter strand. Ground quicklime is also used for the desulfurization of iron in the ladle before charging into the steelmaking furnace.

The major use of quicklime, however, is in the Basic Oxygen Steelmaking (BOS) Process. Its usage varies from about 30 – 50 kg/t of steel. The quicklime neutralizes the acidic oxides, SiO_2, Al_2O_3, and Fe_2O_3, to produce a basic molten slag. Correct formation of the slag is essential for the refining process.

A typical UK specification for steelmaking-quality quicklime is given in Table 2. The $CaCO_3$ content is limited to avoid excessive cooling of the melt through its decomposition to quicklime. The specifications for SiO_2 content and neutralizing value ensure that the quicklime has a high effective CaO content (1 % of SiO_2 neutralizes about 2.8 % of CaO). The grading and reactivity requirements ensure that the quicklime has an adequate surface area and reacts rapidly to produce the slag without excessive loss of fines from the vessel.

Table 2. Quicklime specification for BOS steelmaking

Specification	Criterion	Value
Sulfur	max. average	0.03 %
	maximum	0.04 %
Neutralizing value (CaO)	min. average	95.0 %
	at least 95 % greater than	93.0 %
Silica (SiO_2)	max. average	1.0 %
	maximum	1.5 %
Loss on ignition due to CO_2	max. average	2.0 %
	at least 95 % less than	2.5 %
	maximum	3.0 %
Reactivity (BS 6463)	minimum (at 2 minutes)	46 °C
Grading	nominal top size	38 mm
	nominal bottom size	5 mm
	max. amount passing 6 mm	5 %

Further information on the role of quicklime and the slag in removing phosphorus and sulfur from steel is given in the literature [13].

Calcined dolomite is also added to the BOS vessel to give a slag containing 6 – 8 % MgO, thereby reducing slag viscosity and attack of the basic refractory lining.

The electric arc steelmaking process uses quicklime to react with acidic oxides and produce a molten slag. The specification is similar to that for the BOS process.

Quicklime is also used in the argon oxygen decarburization (AOD) process, for which a −1.5 +0.6 cm product is required with less than 0.15 % C and 0.04 % S.

Calcium carbide (→ Calcium Carbide) is produced by reacting quicklime [14] with coke in furnaces which are heated electrically to 2000 °C. It is used to produce acetylene by reaction with water. The byproduct is an impure form of hydrated lime.

Aerated Concrete. Ground quicklime is used in the production of aerated concrete blocks, with densities of ca. 0.6 – 1.0 g/cm^3. The quicklime is mixed with an active form of silicon (either ground silica sand or pulverized fuel ash), sand, water, aluminum powder and,

depending on the quicklime quality, cement. The reaction of quicklime with aluminum powder generates hydrogen bubbles which cause the mix to rise. At the same time the quicklime reacts with the water, generating heat and causing the mix to set. Close control of the process results in a green set, which enables the semi-solidified mix to be removed from the mold and cut into blocks before autoclaving at elevated temperature and pressure.

The key aspect of the quicklime specification for this use is consistent reactivity (which includes a measure of the total free lime content). The product should have at least 90 % less than 75 µm and its MgO content should preferably be less than 2 %.

Soil Stabilization. Quicklime and hydrated lime can considerably increase the load carrying capacity of clay-containing soils. They do this by reacting with finely divided silica and alumina to produce calcium silicates and aluminates, which possess cementing properties.

Quicklime has the advantage over hydrated lime of drying out the soil. It does this by absorbing 30 % of its own weight of moisture and also by generating heat which accelerates evaporation.

Soil stabilization is used in road and rail construction to strengthen subgrades, thereby reducing construction depths. It may also be used to produce a sub-base in place of aggregate. It is used on clay-rich construction sites for placement and compaction of on-site material. In some countries lime piling is used to pin unstable soils and to provide support for building slabs.

The UK specification for quicklime used in soil stabilization is given in a Department of Transport publication [15].

Other Uses. Small quantities of quicklime are used in other processes [5], e.g., the production of glass, calcium aluminate cement, and organic chemicals. About 50 % of the total production, however, is converted to calcium hydroxide before use (see Section 4.4).

Specifications. Because of the dominance of the steel industry, a high proportion of producers select feedstone, kilns, and fuel which enable them to meet the Basic Oxygen Steelmaking specification (Table 2). Others operate to meet the requirements for building lime [8]. High reactivity is an advantage in soil stabilization. Consistent reactivity is essential in the aerated concrete process. The particle size requirements often depend on the customers' handling, conveying, and blending systems.

4. Hydrated and Slaked Lime

4.1. Physical and Chemical Properties

Color. Most hydrated limes are white. High levels of impurity can result in a gray or buff color.

Density. High-calcium hydrated lime has a density of about 2.24 g/cm^3. The values for partially and fully hydrated dolomitic lime are about 2.7 and 2.5 g/cm^3, respectively.

Bulk Density. The compacted bulk density is in the range 450 to 640 kg/m^3. In the as-poured state, it can be as low as 350 kg/m^3, owing to air entrainment.

Specific surface area may be measured by air permeability [7], or by surface absorption of nitrogen (BET surface area). The former method generally gives areas of 1000 – 2000 m^2/kg; the latter gives results which are some 20 to 30 times greater.

Angle of Repose. In the fluidized state, the angle of repose is 0°. In the compacted state, and particularly with 1 % or more of excess water, the angle of repose can be over 80°. With bunker aeration, valley angles of 70° have proved to be satisfactory.

Hardness. This is between 2 and 3 Mohs.

Specific Heat. The specific heat of calcium hydroxide rises from 1130 J kg^{-1} K^{-1} at 0 °C to 1550 J kg^{-1} K^{-1} at 400 °C [16]. That of dolomitic hydrate is believed to be about 5 % higher [1].

Solubility. This decreases from about 1.85 g $Ca(OH)_2$/L water at 0 °C to 0.71 g/L at 100 °C for commercial calcium hydroxide, depending on impurity levels [17].

Some inorganic compounds affect the solubility [18]. Calcium sulfate is of particular interest; a 2 g/L solution reduces the solubility to 0.06 g $Ca(OH)_2$/L. Organic compounds can increase the "solubility" of calcium hydroxide. Sugar has the greatest effect, as a result of the formation of calcium saccharate [18].

Magnesium hydroxide is only sparingly soluble in water (ca. 0.01 g/L) [19].

Carbon Dioxide. Calcium hydroxide reacts readily with carbon dioxide in the absence of water at temperatures below its dissociation point (ca. 540 °C). The reaction of quicklime with carbon dioxide below 500 °C only proceeds in the presence of some water vapor via formation of calcium hydroxide.

$$CaO + H_2O \longrightarrow Ca(OH)_2$$

$$Ca(OH)_2 + CO_2 \longrightarrow CaCO_3 + H_2O$$

Acid Neutralization. Hydrated lime, whether $Ca(OH)_2$, $Ca(OH)_2 \cdot MgO$, or $Ca(OH)_2 \cdot Mg(OH)_2$, reacts readily with acids and acidic gases. The rate of reaction depends in part on the particle size of the hydrated lime.

Silica and Alumina. Hydrated lime reacts with pozzolans (materials containing reactive silica and alumina) in the presence of water to produce hydrated calcium silicates and aluminates. The reactions may take months to proceed to completion at ambient temperatures (e.g., soil stabilization), but proceed within hours at elevated temperature and water vapor pressures (e.g., at 180 °C and a steam pressure of 1 MPa). This pozzolanic reaction is the basis of the strength generated by hydraulic quicklime.

pH. Because calcium hydroxide is a strong base, a concentration of 0.1 g $Ca(OH)_2$/L gives a pH of about 11.3 at 25 °C. A saturated solution at 25 °C, containing 1.8 g/L, gives a pH of 12.45. The pH of dolomitic hydrate is similar to that of calcium hydroxide.

Thermal Dissociation. Calcium hydroxide decomposes at about 550 °C to quicklime and water. The quicklime so produced has an exceptionally high reactivity to water.

Causticization. Hydrated lime reacts with soluble metal carbonates to produce insoluble calcium carbonate and the metal hydroxide. This reaction is used to produce caustic soda (see Section 4.4).

4.2. Raw Materials

4.2.1. Raw Materials for Hydrated Lime

Hydrated lime can be produced from any quicklime. In commercial practice, however, the quicklime quality should be within well-defined limits to enable the processing plant to be selected to produce salable products economically.

Reactivity. The reactivity of the quicklime should be compatible with the characteristics of the plant.

Thus highly reactive quicklime (over 55 °C, BS 6463) tends to produce a water-burned gritty hydrate with a particle size up to 3 mm. The grit is believed to be formed by very rapid hydration on the surface of a quicklime particle, leading to the production of a putty which bakes into a hard layer and holds the particle together. If the plant includes a mill which has the capacity to grind the product to substantially less than 75 µm, such grit does not present any quality problems.

Quicklime of intermediate reactivity (30–55 °C, BS 6463) generally hydrates well, providing it is given adequate residence time in the hydrator.

Quicklime of low reactivity (below 30 °C, BS 6463) also tends to produce a gritty hydrate, unless given a long residence time. This grit consists largely of particles of unreacted solid-burned lime with a coating of hydrate. This must be ground to substantially less than 75 µm and returned to the hydrator if a fully hydrated product is required. Any free lime eventually hydrates and expands. This can cause expansion in, for example, sand-lime bricks, and may result in cracking, surface defects, and unsoundness in, for instance, plaster.

Calcium Carbonate. The permissible $CaCO_3$ content of the feed quicklime depends on whether the plant is designed to reject a fraction rich in $CaCO_3$ and on the $CaCO_3$ specification for the finished hydrated lime. In some cases, with a hydrated lime specification of 2 % $CaCO_3$, feed quicklime $CaCO_3$ levels of up to

10 % can be accepted; in others the level must be below 2.6 %. The $CaCO_3$ is removed by screening or air classification.

Particle Size. The particle size of the quicklime fed to hydrators is generally below 5 cm and often as low as 0.6 cm, depending on the design of the plant.

Magnesium Oxide. As MgO is not readily hydrated, the normal hydration process does not convert it to the hydrate. Providing the MgO content is below about 2 %, the consequent unsoundness and expansion potential do not present problems. Higher MgO contents limit the markets into which the hydrated lime can be sold. Quicklimes with high MgO contents are often hydrated in the autoclave process, which produces a fully hydrated product with a high plasticity (see Section 4.3).

Other Impurities. Some applications limit the permissible levels of impurities in hydrated lime, which in turn place constraints on the impurities in the feed lime. These include lead, iron, silicon, and fluorine (see Section 4.4).

4.2.2. Raw Materials for Slaked Lime

In the slaking process, quicklime is reacted with a controlled excess of water to produce a milk or putty. The quicklime should be such that it gives the required quality of milk or putty and is compatible with the design of slaker used.

Reactivity. It is generally necessary to specify the reactivity to match the characteristics of the slaker and to obtain the required physical properties of the milk or putty.

Calcium Carbonate. Although many slakers remove grit rich in $CaCO_3$ by settling or filtration, their capacity to do so is limited. Therefore, the $CaCO_3$ content should also be limited. In other slakers, most or all of the $CaCO_3$ in the quicklime is included in the slaked lime; the $CaCO_3$ content should be compatible with the acceptable level in the slaked lime.

Particle Size. This is generally determined by the handling and processing equipment. In some cases a −2 cm quicklime is required. In others a ground quicklime is specified.

Magnesium Oxide. In applications where unsoundness or expansion potentials must be low, the MgO content in the quicklime should be below 2 %.

Water. The presence of impurities in water can have a marked effect on the reaction of quicklime with water in the reactivity test (see Section 6). However, water quality does not generally affect the industrial production of slaked lime.

Restrictions on other impurities in the quicklime are as for the production of dry hydrated lime.

4.3. Production

4.3.1. Normal Hydration Process

The normal hydration process, leading to the production of Type N hydrate, as defined in ASTM specification C-207 [2], is carried out at atmospheric pressure and ca. 100 °C. There are many designs of equipment, the choice of which depends on the reactivity and chemical purity of the quicklime, its particle size, and on the requirements for the finished product.

In a typical plant, the quicklime is mixed rapidly with about twice the stoichiometric amount of water in a premixer and is then passed into the main hydrating vessel, which is agitated and fitted with a weir at the discharge end to give an average solids residence time of 10 – 15 min.

As the hydration reaction proceeds, part of the water boils off vigorously, producing a partially fluidized bed. Coarse particles of gritty hydrate, unreacted lime, or unburned limestone are retained behind the weir, while fine particles of hydrate flow over it. In some plants a purge paddle close to the weir prevents excessive build up of coarse particles by lifting them over the weir. In others the coarse fraction is periodically rejected through a purge hole in the weir.

The raw hydrate is then conveyed along one or more tubes, which serve to complete the hydration and evaporate excess water. The hydrate is discharged at about 90 °C and contains less than 1 % excess water.

The raw hydrate is fed to an air classifier, in which a recycling air stream removes fine particles into an outer settling chamber and allows coarse particles to fall to the base of the inner feed chamber. The fine particles make up the finished product. The coarse particles may then be rejected as a stream rich in $CaCO_3$. Alternatively, they may be milled, with the product being recycled to the hydrator, added to the fines from the air classifier, or reclassified.

The steam generated in the hydrator, together with any air drawn into the process, may be dedusted in a wet scrubber before discharge to the atmosphere, in which case the milk of lime from the scrubber is fed to the premixer.

Some plants use aging silos to retain damp hydrate at elevated temperature for about 24 h to increase the extent of hydration. They are generally used when the feed quicklime has a low reactivity; with dolomitic hydrate; or when a product with a particularly low expansion potential is required.

4.3.2. Pressure Hydration Process

Type S hydrate, as defined in ASTM specification C-207 [2], is produced by reacting quicklime (generally dolomitic) and water under a steam pressure of up to 1 MPa and at a temperature of up to 180 °C. After hydration the product is dried, milled, and air classified.

4.3.3. Production of High Surface Area Hydrated Limes

Processes have been developed for the production of high-surface hydrated limes for injection into flue gases to remove acid gases [5]. One process hydrates the quicklime with an amine/glycol additive in a largely conventional plant [61]. Another uses a water/methanol mixture [62].

4.3.4. Normal Slaking Process

There are many ways of slaking quicklime, ranging from the batch process to sophisticated continuous slakers.

In the batch process, water and quicklime are added as required to maintain the milk at about 90 °C. With reactive quicklime, care should be taken to avoid local overheating which can lead to water-burning and a gritty hydrate (see Section 4.2.1). With cold water, this technique produces a viscous suspension with 35 – 40 % solids. Grit arising from uncalcined limestone and from unreacted and water-burned lime settles on the floor of the vessel.

There are various designs of continuous slakers, which produce either milk of lime or lime putty. Some feature automatic grit removal.

Slaking at ca. 90 °C produces the finely divided particles of calcium hydroxide required by most users. If the slaking temperature drops, e.g., to 70 °C, the resulting increase in particle size can reduce both the viscosity and reaction rate.

Aging the slaked lime for 30 min generally ensures complete hydration. Aging for a day generally improves the physical properties, e.g., higher viscosity and greater workability.

4.3.5. Production of Ultrafine Milks of Lime

Two processes have been developed for the production of ultrafine milks of lime [5]. Such milks dissolve very rapidly, can be processed more as liquids than suspensions, and can have beneficial rheological properties. They are produced by slaking at high shear rates [63] or by milling in a bead mill.

4.4. Uses and Specifications

4.4.1. Uses

In this Section, the term hydrated lime is used to describe both dry hydrate and slaked lime, unless otherwise specified.

There is little reliable information about the proportion of quicklime which is hydrated before use. The author's estimate for European countries is that it is roughly 50 %, of which about one-third is initially converted into dry hydrated lime and two-thirds are initially slaked to give milk of lime or lime putty.

Hydrated lime is used in a large number of processes. The more important ones are described briefly below. More detailed information is available in the literature [5].

The Solvay Process. A key step in the Solvay (or ammonia-soda) process for the production of soda ash and sodium hydrogen carbonate is the recovery of ammonia from an ammonium chloride solution by reaction with milk of lime.

$$2\,NH_4Cl + Ca(OH)_2 \longrightarrow 2\,NH_3 + CaCl_2 + H_2O$$

Causticization. Caustic soda can be produced by reacting sodium carbonate with milk of lime. Before the development of the electrolytic cell, this was the normal method of production of caustic soda.

$$Na_2CO_3 + Ca(OH)_2 \longrightarrow 2\,NaOH + CaCO_3$$

In addition to its use in the Bayer alumina process (see below) this reaction is used for the regeneration of caustic soda in wood pulp plants for the production of kraft or sulfate paper.

Nonferrous Metallurgy. Hydrated lime is used in the production of alumina by the Bayer process to regenerate sodium hydroxide from sodium carbonate solutions (see above). It is used in flotation processes to beneficiate copper ore and to extract gold and silver. It is an essential chemical for the extraction of uranium from gold slimes and for the recovery of nickel and tungsten after smelting.

Hydrated lime is used in the production of magnesia. In the seawater processes, a high-calcium hydrate is used to precipitate magnesium hydroxide, while in the Dow natural brine process, dolomitic hydrated lime is used.

Water Treatment. Hydrated lime is used to remove both carbonate (temporary) and non-carbonate (permanent) hardness. Calcium and magnesium hydrogen carbonates react with calcium hydroxide to produce insoluble calcium carbonate and magnesium hydroxide.

$$Ca(HCO_3)_2 + Ca(OH)_2 \longrightarrow 2\,CaCO_3 + 2\,H_2O$$

$$Mg(HCO_3)_2 + 2\,Ca(OH)_2 \longrightarrow Mg(OH)_2 + 2\,CaCO_3 + 2\,H_2O$$

Non-carbonate hardness caused by calcium and magnesium chlorides and sulfates can be removed by hydrated lime plus sodium carbonate.

$$CaSO_4 + Na_2CO_3 \longrightarrow CaCO_3 + Na_2SO_4$$

$$MgSO_4 + Ca(OH)_2 + Na_2CO_3 \longrightarrow Mg(OH)_2 + CaCO_3 + Na_2SO_4$$

Water can be purified by raising the pH to above 11 for 1 – 2 d, followed by recarbonation to pH 8 – 9. In addition to killing bacteria, this treatment removes temporary hardness. Acid water may be neutralized by the addition of lime. Specifications have been published for limes used in the United States for water treatment [14], [20]. Corresponding European standards are in preparation [48–50].

Sewage Treatment. Treatment of sewage sludge with hydrated lime in conjunction with ferrous sulfate is an effective way of removing solids and phosphorus compounds, and for destroying pathogens. It produces a sludge which dewaters well and can be used as a fertilizer.

Industrial Wastes. Hydrated lime is used widely to neutralize acid wastes and precipitate heavy metals in effluents from a wide range of industries. In some cases it is also used to assist with the clarification process.

Flue Gas Desulfurization. Of the many flue gas desulfurization processes, three use hydrated lime.

In the wet scrubbing process, milk of lime is sprayed through the gases. The product is a suspension of calcium sulfite, which may be oxidized to produce salable gypsum. Up to 95 % removal of sulfur dioxide has been reported, with over 90 % utilization of the hydrated lime [21].

In the dry scrubbing process, milk of lime is fed into a spray drier from which the product is a dry powder consisting of calcium sulfite and hydrated lime. Up to 85 % removal of sulfur dioxide and 40 – 60 % utilization of the hydrated lime have been obtained [21].

Sulfur dioxide may also be removed by injection of dry hydrate either into the boiler, or downstream from the boiler. The reaction products are collected with the fly ash for disposal. Only 50 – 60 % of the sulfur dioxide is removed, and the utilization of normal hydrated lime is

less than 40 % [21]. Hydrated lime products with higher specific surface areas than those of normal hydrated lime have been developed for this use.

Sugar Refining. In the refining of sugar beet, the crude solution of sugar is treated with milk of lime to precipitate calcium salts of organic and phosphoric acids. After filtering, the solution is neutralized with carbon dioxide, calcium carbonate is removed by filtration, and a purified sugar solution is produced.

As the process requires large quantities of both lime (about 250 kg/t of sugar) and carbon dioxide, producers of sugar from beet generally operate their own lime kilns as part of their process.

Because cane sugar is purer, its refinement requires much less hydrated lime (typically 5 kg/t).

Sand – Lime Bricks. There is a substantial market in Europe for sand – lime bricks. These are made by mixing hydrated lime with sand, followed by autoclaving for several hours under a steam pressure of ca. 1 MPa (180 °C). In some processes, it is essential that the hydrated lime is not expansive, because the expansion can occur in the autoclave and result in the production of oversize bricks.

Mortars. Hydrated lime is used in lime – cement – sand mortars in various proportions. The required compressive strength of the mortar is obtained by adjusting its composition [51]. The lime confers several benefits. It increases the plasticity and water retentivity of the wet mortar and increases the bond strength of the mortar to the masonry. The mortar is more flexible and less prone to cracking.

Soil Stabilization. Both dry hydrated lime and milk of lime are used in soil stabilization. Dry hydrate disperses readily when making a soil tilth. Milk of lime has advantages when the soil is dry; it can also be injected under pressure.

Agriculture. The advantages of adjusting soil pH with limestone are described in Section 2.4. Hydrated lime has the additional advantage of being quick acting.

Bleaching. Chlorine is reacted with hydrated lime to produce a powdered mixture of calcium hypochlorite and calcium chloride, commonly known as bleaching powder.

$$2\,Ca(OH)_2 + 2\,Cl_2 \longrightarrow Ca(OCl)_2 + CaCl_2 + 2\,H_2O$$

Calcium hypochlorite solution is used in bleaching wood pulp.

Precipitated calcium carbonate (PCC) is produced by blowing gases containing carbon dioxide through milk of lime. By controlling the conditions, a very finely divided calcium carbonate with a high reflectivity and a median particle size of 0.02 – 0.2 µm is produced. Some PCC's are coated with compounds which facilitate their blending with organic substancs (e.g., plastics and rubber).

Inorganic Salts and Bases. Hydrated lime is used in the production of mono-, di-, and tricalcium phosphates as well as other calcium salts. It is used in the Solvay process to produce calcium chloride as a byproduct. Lithium and barium hydroxides are made by causticization.

The brine purification process uses sodium carbonate and milk of lime to remove dissolved calcium and magnesium.

Other Uses. There are a wide range of other uses such as the production of calcium silicate insulation products, plasters, lubricants, pigments, soda lime, organic compounds and calcium salts. Hydrated lime is also used in the petroleum industry, glass manufacture, solid waste disposal, and leather tanning [5].

Table 3. Typical specification for high-calcium hydrated lime [8]

Specification	Criterion	Value
Carbon dioxide	maximum	12 % ∗
CaO + MgO	minimum	70 % ∗
MgO	maximum	5 % ∗
Residue on 180 µm	maximum	2 %
90 µm	maximum	7 %
Soundness		
expansion	maximum	20 mm
pat test	pops or pits	nil
Excess moisture	maximum	2 %

∗ Based on a water-free and bound-water-free product.

4.4.2. Specifications

In many countries, the most widely recognized specifications for dry hydrated lime relate to its use in building [2], [8]. These set minimum values for fineness, neutralizing value, and other properties. In practice, most dry hydrated limes meet these requirements with ease. A typical quality specification is given in Table 3.

Some end uses require especially low levels of impurities such as silica, iron oxide, magnesium oxide, and fluoride. Others require uniform surface areas.

Dry hydrated lime for use in the production of sand – lime bricks should have an expansion below 10 mm [22] and less than 4 % MgO (unless it is Type S).

5. Environmental Protection

5.1. General

The main environmental issues associated with the production of lime and limestone products are air pollution and energy consumption; the latter is described in Section 3.3.2. Dust emissions can arise from the crushing and handling of limestone and the burning, processing, and handling of quicklime and hydrated lime. In certain circumstances, the emission of sulfur dioxide and oxides of nitrogen can be an issue for rotary kilns, but that is rarely the case for shaft kilns. These and related topics are addressed in some detail in [23], [24].

5.2. Dust Emission

Standards. In many countries, emissions of dust to the atmosphere for new equipment are limited to 50 mg of solids per cubic meter (at 0 °C and 101 MPa).

Equipment. A variety of techniques are used to control dust emissions from stone processing operations. Dust suppression, which uses water with a wetting agent, causes dust to adhere to larger particles. It can be an effective and inexpensive method but can cause undesirable surface contamination of screened products with fines and increase downstream dust problems.

As the effluent gases from stone processing and local exhaust ventilation systems are generally at relatively low temperatures, bag filters or high-energy wet scrubbers are widely used. The dust collected by bag filters can often be sold as a filler for concrete production.

The temperature of the effluent gases from lime kilns is commonly 200 – 400 °C. In the past, high efficiency multi-cyclones were widely used to collect the dust. They had the advantage of being relatively inexpensive to install and operate. However, their efficiency is generally no longer adequate in the context of current emission requirements.

Electrostatic precipitators can handle gases at the above temperatures. Although their capital cost is high, their operating costs are moderate.

Gravel bed filters can be operated at high temperatures. They can be efficient but have higher capital and operating costs than electrostatic precipitators. Consequently, they are not widely used.

Bag filters are widely used when the gas temperatures are below 200 °C. They are lower in capital cost than precipitators, have a high collection efficiency, but have high operating costs. The reverse-jet method of cleaning the bags has generally been found to be the most effective.

The dust collected from lime kilns is generally high in $CaCO_3$ but also contains quicklime and possibly fuel ash. In some processes it is blended in a controlled manner into selected products; in others it is used for landfill

Wet collectors are not widely used with quicklime. They are, however, generally the preferred method of controlling dust from hydrating plants. The collected milk of lime is fed back to the process.

Dust collection from the handling, storage and loading of quicklime and hydrated lime generally involves bag filters. The collected dust usually has a high lime content and is sold.

5.3. Gaseous Emissions

In most lime kilns, *sulfur dioxide* emissions are acceptably low [e.g., < 500 mg SO_2/m^3 (STP)]. This is because the quicklime captures and retains a high proportion of the sulfur from the fuel and limestone. However, when low-sulfur quicklime is produced in rotary kilns, and hard-burned

calcium lime/dead-burned dolomite is produced in shaft or rotary kilns, most of the sulfur may be emitted with the exhaust gases. In such situations, there may be a need to abate the emission of sulfur dioxide. The only proven sulfur dioxide abatement technique for lime kilns is to use a fuel with a lower sulfur content. Sulfur dioxide abatement techniques used in other industries include the injection of calcium hydroxide into the exhaust gases. As yet, however, their application to lime kilns is unproven.

Most shaft kilns emit acceptably low concentrations of *nitrogen oxides* [e.g., < 500 mg NO_2/m^3 (STP)] when producing light- and medium-burned quicklime. However, when they are used to produce hard-burned calcium lime and dead-burned dolomite, higher emissions result. Emissions from rotary kilns producing soft-burned lime are generally acceptable, but increase to > 800 mg NO_2/m^3 (STP) when medium-, hard-, and dead-burned products are made. Currently (1999), there are no proven abatement techniques for lime kilns. Techniques used in other industries include low-NOx burners, selective noncatalytic reduction, and selective catalytic reduction, but their applicability to lime burning has yet to be established.

Significant emissions from lime kilns of *other substances*, such as volatile organic compounds, dioxins, and furans, are only likely to occur under exceptional circumstances [24]. There is no evidence of significant emissions of heavy metals.

5.4. Noise and Vibration

Blasting can produce powerful impulsive sound waves which can startle neighbors and cause buildings to vibrate. The sound level can be focused under certain atmospheric conditions, particularly temperature inversions. Advice has been published on good operating practice to mitigate this effect [25].

Mobile equipment, such as drills, mechanical shovels, and dump trucks, can produce unacceptable noise levels if not adequately silenced. A major problem with fixed plant is the sound produced by the impact of stone on metalwork. Appropriate control measures should be adopted [26].

Increasingly, exhaust fans associated with lime kilns are being designed to be more efficient and to generate more intense suction. These trends can increase the pure-note component generated within the fan and often necessitate the fitting of silencers. The problem of silencing the fans is complicated by the dust present in the gas; reactive silencers have proved to require less maintenance than absorptive designs.

The major source of vibration is blasting. The measurement and control of vibration is well understood, and there are established guidelines relating to complaint levels [27] and to the risk of damage to property [28].

6. Physical Testing and Chemical Analysis

6.1. Sampling and Sample Preparation

The most common cause of disagreement between laboratories arises from the failure to obtain representative samples. Sampling solids, and particularly granular solids made from naturally occurring minerals, is especially difficult. The problem is compounded when, as in the case of quicklime, the quality of the sample is affected by exposure to the atmosphere. In general, if quicklime contains 1 % or more of combined water, it has not been correctly handled, and its reactivity to water will have been reduced.

Guidance on the sampling of limestone, quicklime, and hydrated lime is given in BS 6463, Part 101 [7]. Similar advice is given in ASTM C 110 and C 50 [9], [30]. The sampling of aggregate and the reproducibility and repeatability of test results is described in BS 812 [31].

Samples should be taken from a falling stream whenever possible. Precautions should be taken to ensure that segregation within the stream does not lead to bias. Samples may also be taken from conveyor belts; precautions are required to obtain a representative sample. It is very difficult to obtain a representative sample from the body of a truck or from a stockpile. Careful checks should therefore be made to establish whether the sampling method is valid.

Each sample should consist of not less than ten increments. Each increment should be of an adequate volume (e.g., 10 L for lumps with a maximum size of 10 cm, decreasing to 2 L for

a maximum size of 1 cm, and to 1 L for powders). There are many mechanical aids to sampling ranging from augers to automatic samplers [32].

Some physical tests are performed on the sample as taken. For other physical tests and for chemical analysis, it is necessary to crush, subdivide and pulverize the product to less than 300 µm. This should be done on a separate sample in such a way as to avoid bias and, in the case of quicklime and hydrated lime, to avoid excessive exposure to the atmosphere.

All quicklime and hydrated lime samples should be stored in well sealed containers or bags. It is good practice to double-wrap samples which are to be stored for prolonged periods. Quicklime should not be stored in a desiccator because it removes water from some commonly used desiccants.

6.2. Physical Testing

Limestone. A series of CEN standard physical test methods for aggregates is being prepared. It consists of four standards (in a total of 32 parts) [52–55].

Quicklime and Hydrated Lime. Physical test methods for building lime are given in EN 459 [8]. Additional test methods (residue on slaking, specific surface area by air permeability, and workability of putty) are specified in BS 6463 Part 103 [7]. The corresponding US standard is ASTM C110 [9].

6.3. Chemical Testing and Analysis

Tests for the chemical properties of aggregates are given in EN 1744 [22].

The methods for chemical analysis of limestone, quicklime, and hydrated lime are closely related. The relevant standard for building limes is EN 459-2 [8], which adopts five methods from EN 196-2 [6]. The standard for products used in the preparation of water for human consumption, EN 12485 [12], describes a number of tests, including determinations of minor and trace elements. The British Standard BS 6463, Part 102 [7] specifies additional methods (including minor and trace element determinations) and provides cross-references to the EN standards. Test methods are specified in ASTM C 1271, 1301 and 1318 [56–58].

7. Storage and Transportation

Limestone. Screened sizes of limestone are stored in bunkers and in outside stockpiles. Fine grades are generally stored in sealed bunkers.

As most screened limestone is distributed to a large number of sites, generally within 40–80 km of the quarry, it is mainly transported in sheeted tipper road vehicles. Use of rail or water transport becomes more economic as the volume of business to a given site increases and as the distance becomes greater. It has been estimated that over 75 % of limestone is transported by road [1]. Fine grades of limestone are transported by air pressure discharge vehicles, generally by road, but suitable railroad cars are also available.

Quicklime. Quicklime is stored in enclosed bunkers with well-sealed discharge mechanisms to minimise the reaction with atmospheric water and carbon dioxide and to control dust emission. Storage capacities equivalent to 2 to 5 days' production are usually necessary.

Screened grades of quicklime (generally 0.5 cm and above) may be transported in tipper trucks. Effective sheeting is essential to minimize atmospheric attack on the quicklime and to control dust emission. Air pressure discharge vehicles are used to transport fine grades of quicklime (below 0.5 cm) and, increasingly, screened grades up to 2 cm. Where appropriate, use of rail or water transport can extend the economic delivery distance.

A small amount of quicklime is packaged. Plastic containers and sacks are used for amounts up to 50 kg. Intermediate bulk containers, both rigid and flexible, are being used increasingly for quantities up to 1 t. There is a small international market for packaged quicklime.

Where totally enclosed bunkers cannot be provided, quicklime should be stored on a concrete base, preferably in a separate bay within a building. It should be used as soon as possible after delivery. It can be kept longer by covering the pile with a close-fitting impermeable

Table 4. Main uses of limestone (including dolomite and chalk)

* Mainly concrete and roadstone; excluding cement. ** Mainly for iron and steel production.

sheet. Open reception hoppers should be protected from the elements.

Contact of quicklime with flammable materials should be avoided, especially when there is a risk of water penetration. In the presence of organic matter, the heat of hydration has been known to cause fires.

Further details on the delivery, storage and handling of quicklime are often available from the supplier (see also [60]).

Hydrated Lime. Hydrated lime is stored in enclosed silos to minimize reaction with atmospheric carbon dioxide and to control dust emission.

Most hydrated lime is transported in air pressure discharge vehicles, both by road and rail. A substantial amount, however, is sold in paper sacks (generally 25 kg in the United Kingdom) Use of intermediate bulk containers holding up to 1 t is increasing. There is a significant international market for packaged hydrate.

The flow characteristics of hydrated lime are very variable. The angle of repose varies from 0 – 80° according to the amounts of entrained air and excess water, and other factors. Silos may need to be fitted with devices to cope with bridging of the powder above discharge points and to encourage flow (e.g., bin activators and air pads).

Hydrated lime in paper sacks is generally placed on pallets and stored under cover. By fitting impermeable slip sheets under the bags and shrink wrapping a cover over the loaded pallet, it may be stored out of doors for several months.

Further details on the delivery, storage and handling of hydrated lime are often available from the supplier (see also [60]).

8. Economic Aspects

Limestone is a major mineral product. Statistics on its production are not widely available and are often complicated by the inclusion of other crushed rocks. It is estimated that the worldwide production is over 4500×10^6 t/a. Table 4 gives tonnages for sales in the United States, Germany, Japan, and the United Kingdom, and the distribution of those sales between the major market segments. The high percentages of limestone used in construction and building in the United States and the United Kingdom reflects the relatively high availability of limestone in those countries when compared with Germany and Japan.

The physical and chemical qualities of limestones affect the applications for which they are used. Table 5 summarizes the quantities of dense, high-calcium limestone, dolomite, and chalk consumed in the UK in the main market segments [41]. Ex-works prices for limestone aggregate are in the range £ 2 to £ 5/t (1999). Chemical-quality limestone for lime burning, glass manufacture, and flue gas desulfurization commands prices in the range £ 5 to £ 10/t.

Ground limestone products (or whiting) typically sell for £ 25 to £250/t, depending on the fineness and quality. Precipitated calcium carbonate (PCC) is a specialist chemical which can command prices of £ 250 to £ 1000/t.

Quicklime and Hydrated Lime. Published estimates of the global production of lime products [56], [59] suggest a volume of ca. 120×10^6 t/a. The major producing countries are listed in Table 6. The published figures do not include the many captive producers and the multitude of small producers in the developing countries. It has been estimated that if their contribution were included the total would probably exceed 300×10^6 t/a.

Table 6. Estimated Lime Production in Various Countries (1994)

Country	Total production *
Australia	1 250
Austria	700
Belgium	1 750
Brazil	5 700
China **	19 500
Czech Republic	1 200
Denmark	130
Finland	300

Former USSR	16 000
Others (by difference)	8 380
Estimated world total	118 000

* The above estimates are based on published values for open-market production [56], [57], [59].
** Estimates of over 100×10^6 t for China have been reported [44], but not substantiated.

Table 7 summarizes the use of lime products in the various market segments in nine countries [56–58].

The ex-works price of screened high-calcium quicklime products in Europe is generally in the range £ 40 to £ 60/t (1999). In the United States, the average ex-works price for screened high-calcium quicklime was $ 57/t (1998) [59]. Ground quicklime and hydrated lime prices are typically some 30 % higher than those of screened quicklime, reflecting the capital and operating costs of the additional processing stages (e.g., in the United States, the average 1998 price of high-calcium hydrated lime was $ 75/t). Specialist products, tailored to the needs of individual market segments or customers, also tend to command higher prices.

9. Toxicology and Occupational Health

9.1. Toxicology

Limestone is a practically nonharmful material, providing its content of crystalline silica is less than 1 %.

As an air-borne dust, its long term exposure limit (8-h TWA) is 10 mg/m^3 of total inhalable dust and 5 mg/m^3 of respirable dust [42]. Lower limits apply if the content of crystalline silica exceeds 1 %.

As with other nuisance dusts, limestone may irritate the eyes and cause discomfort. It can also cause discomfort as a result of its drying effect on the mouth and upper respiratory tract. It is nonirritant to the skin.

Limestone is used in the treatment of water for human consumption. In such applications, limits may be applied to the minor and trace element contents [50]. Calcium carbonate is a recognised ingredient of human and animal foodstuffs. It is used as an antacid. The therapeutic dose is 1 – 5 g. Chronic effects are unlikely to be encountered in industry. There are no occupational diseases known to be connected with the handling of limestone.

Quicklime and hydrated lime are alkaline in the presence of water (pH 12.4). In addition, when quicklime comes into contact with water, it generates a considerable amount of heat.

As airborne dusts, the long-term exposure limits (8-h TWA) for quicklime and hydrated lime are 2 and 5 mg/m^3, respectively [42]. The

Table 7. Percentage of lime products in the main market segments (1994)

[c] Mainly potable water, sewage, liquid and gaseous effluent treatment.

dusts are irritating to the respiratory tract and may cause inflammation. Contact of lime with the eyes can cause painful irritation and may result in serious damage unless immediate treatment is given.

Both quicklime and hydrated lime are classified as irritant and can cause "chemical burns" of the skin, when subject to abrasion in the presence of moisture, or perspiration. Under the EEC Dangerous Preparations Directive, both products are classified by risk phrases R38 (irritating to skin) and R41 (risk of serious damage to eyes). Prolonged and repeated contact may cause the skin to become dry and cracked, and may lead to dermatitis. Ingestion can cause corrosion and damage to the gastrointestinal tract.

Both quick- and hydrated lime are used in the treatment of drinking water. In such cases, limits may be applied to the minor and trace element contents [48], [49].

9.2. Occupational Health

Limestone. The quarrying industry in general has a poor safety record relative to general manufacturing [43]. In the United Kingdom, mobile equipment (shovels, dump trucks, etc.) is the major cause of deaths. The second largest cause of deaths and over half of the major injuries is stumbling, falling, and slipping. While the use of explosives is generally perceived to be a major hazard, it causes less than 5 % of the UK deaths and major injuries, presumably because it is well covered by legislation.

In limestone mines, rock falls are the major cause of deaths and serious injuries, and mobile equipment is the next most significant category. Special electrical precautions (e.g., high-integrity earthing and the use of low-voltage portable tools) are essential, as water percolates into most limestone mines [45].

Stone processing involves a number of mechanical operations. The largest category of injuries caused by these generally arises from inadequate guarding of machinery and from failure to electrically isolate equipment when carrying out maintenance and clearing blockages [44].

Many stone-processing operations produce high sound levels. Operators' exposure to noise is controlled by a combination of reduction and containment at source, excluding it from control rooms, and the use of remote cameras with monitors in control rooms. Effective personal hearing protection is still required when operators are required to enter noisy areas.

Ways of controlling in-plant dust arising from quarrying and stone processing are mentioned in Section 5.2.

Quicklime and Hydrated Lime. The lime industry generally has a lower accident rate than quarrying. Contributory factors are likely to be the reduced use of mobile equipment and the greater size of the works (there is a correlation between accident rate and the number of people employed on site [47]). Tripping and falling constitute the largest category of accidents.

Lime processing involves a number of mechanical operations. Adequate guarding of

moving machinery and effective isolation procedures when carrying out maintenance are essential.

Both quicklime and hydrated lime are dusty, alkaline products. Not surprisingly, a common injury arises from grit or dust entering the eye. It is advisable to wear eye protection at all times in lime plants. Techniques to control in-plant dust are mentioned in Section 5.2.

1. Introduction

The term liquefied petroleum gas (LPG) describes hydrocarbon mixtures in which the main components are propane, butane, isobutane, propene, and butenes. Most commonly this term is applied to mixtures of propane and butane. These components and mixtures thereof are gaseous at normal temperature and pressure but can be liquefied by cooling, compression, or a combination of both processes.

Liquefied petroleum gas is produced from two distinct sources. The first is by *extraction* from crude oil and natural gas streams at or close to the point of production from the reservoir and contains propane and butane. The quantities of LPG in the well stream fluid vary greatly, depending on the nature of the reservoir. Production may be (1) of natural gas from a gas reservoir, (2) of gas and light liquid hydrocarbons from a gas condensate reservoir or (3) of crude oil and gas from a combined oil and gas field. The extent of recovery of LPG and heavier hydrocarbons from gas depends on the composition of the gas produced and the quality specifications of the gas to be transported to the consumer. Before storage or transportation of crude oil by tanker, its vapor pressure must be lowered so that it can safely be contained in a ship's tank. This reduction, known as stabilization, is achieved by the removal of LPG and lighter species to yield stabilized crude oil and additional natural gas (see Fig. 1). The LPG components in produced oil and gas are predominantly the saturated hydrocarbons propane, butane, and isobutane.

Second, LPG is obtained by *processing* of crude oil in refineries and in some instances as a byproduct from chemical plants. The remaining LPG in the stabilized crude oil at the refinery is separated in the crude oil fractionation column. The constituents of this LPG are propane, butane, and isobutane. Additional LPG is produced in refinery conversion processes such as catalytic reforming, thermal cracking, catalytic cracking, and hydrocracking (see Fig. 2). The composition of this LPG depends on the processing configuration at the refinery but typically includes both saturated (propane, butane, and isobutane) and unsaturated (propene and butenes) components.

Table 1. Physical properties of the main LPG components [4]

	Boiling point (101.3 kPa), °C	Vapor pressure (37.8 °C), kPa	Liquid density (at saturation pressure; 15.6 °C), kg/m^3	Gross calorific value (25 °C), kJ/kg

2. Properties

The physical properties of the main constituents of LPG are listed in Table 1. In addition to these components, other species may be present in trace quantities. Typically, sulfur compounds, water, and occasionally residual oils and tars may occur. Depending on the use of the LPG, these contaminants must be reduced to an acceptable level, commensurate with the applicable LPG specifications in the country of use.

3. Production and Processing

Recovery from Natural Gas. Natural gas consists largely of methane (→ Natural Gas) and smaller quantities of ethane, propane, butanes, and heavier hydrocarbons, together with varying amounts of water, carbon dioxide, nitrogen, sulfur compounds, and other nonhydrocarbons. Depending on the specifications of the gas supplied to the consumer, a proportion of the ethane and heavier component content is recovered in gas processing plants, which yield additional products such as ethane, LPG, and higher boiling hydrocarbons (natural gasoline). When no

incentive to recover ethane exists, only the LPG and natural gasoline are recovered from natural gas. Increasingly, however, ethane is considered a valuable product in the petrochemical industry, and plants are designed to recover not only LPG but also ethane. Potentially all of the ethane, LPG, and natural gasoline may be obtained as products from natural gas; however, some ethane must normally remain in the gas to meet sales specifications.

Recovery and Manufacture in the Refinery (→ Oil Refining). After crude oil has been stabilized for transportation to the refinery, small but significant amounts of LPG and lighter components (methane, ethane) remain in the oil. In the refinery, crude oil is first separated into a number of fractions by distillation (fractionation). Gas, which is the lightest fraction, is produced as the top product from the atmospheric fractionation column; it consists of LPG, ethane, and methane. Other fractions that contain the main refinery products are, in order of ascending atmospheric boiling points, naphtha, kerosene, gas oil, and residue.

In practice, the yield of each fraction does not match market demand. Consequently, the less valuable heavy fractions must be converted into lighter ones, and the lighter fractions must be chemically modified to improve their properties. Examples of these conversion processes are catalytic reforming, catalytic cracking, thermal cracking, hydrocracking, and alkylation.

The products of *thermal* and *catalytic* cracking include LPG and lighter components (ethane, ethylene, methane, hydrogen), both saturated and unsaturated. Conversely, during *catalytic reforming* and *hydrocracking* only saturated LPG and lighter components are formed. Generally, the products of these conversion processes are separated in a fractionation column to yield gas and the main products. Thus, gas streams consisting of LPG and lighter components are produced from direct fractionation of crude oil and from fractionation of the products of various refinery conversion processes.

These gas streams are used as fuel gas for refinery furnaces. However, LPG normally has a significantly higher economic value than fuel gas, and recovery of LPG is economically attractive. On the other hand, the most effective use of ethane in the refinery is as fuel gas because normally no incentive exists to recover ethane.

Depending on circumstances, various techniques may be used for the recovery of LPG which can be applied in gas plants or refineries. These methods are: (1) recontacting – compression, (2) refrigeration, (3) absorption, (4) adsorption, or (5) a combination thereof.

3.1. Recontacting – Compression (Fig. 3)

The overhead vapor product from the fractionator (a) is compressed to 1.2 – 1.5 MPa (c) and combined with the liquid top product, as shown in Figure 3. The combined stream is cooled to ca. 40 °C by air or water and directed to the separator (e). Because of the higher pressure, more LPG is obtained in the liquid phase of the separator than in the liquid phase in the overhead accumulator vessel (b) of the fractionator. Components heavier than butane are also recovered from the fractionator vapor top product by recontacting. The liquid phase from the separator passes through a deethanizer (f), from which the vapor product is recycled to the separator to improve LPG recovery. The vapor phase from the separator, which still contains some LPG, is used as fuel gas. The liquid product from the deethanizer is LPG, which may be further separated into propane and butane products in a depropanizer.

Recontacting – compression achieves ca. 75 % recovery of the LPG in the fractionator overheads. In gas processing plants, this technique is hardly used today because better recovery of LPG is almost always required.

3.2. Refrigeration

The recovery of LPGs from a gas stream can be accomplished by a variety of techniques. The most common technique applied in new LPG recovery plants is to refrigerate the gas stream to condense the LPG fraction. The recovered liquids are then fractionated to separate the LPG components.

Some of the most commonly employed processes are summerized below.

3.2.1. Low-Temperature Separation (LTS)

Refrigeration of an LPG containing gas stream can be accomplished by indirect heat transfer with an external refrigerant stream. In a conventional gas conditioning plant, refrigeration is normally provided by a closed-loop propane refrigeration circuit (see Fig. 4). Treated and dried feed gas to the plant is first contacted with cold LPG lean gas exiting the plant (a). The precooled gas is then further cooled by propane chilling to condense the LPG fraction in the feed gas (b). The condensed liquids are then recovered in the HP separator (c) and fed to a downstream fractionation plant. Cold from the lean gas exiting the HP separator is then used for cooling the feed gas.

The liquids from the HP separator are fed to a conventional fractionation plant comprising a demethanizer, deethanizer, depropanizer and

debutanizer for separation of the LPG components. If no extra ethane outlets are available, then the demethanizer and deethanizer column can be combined to a single column. The chief advantages of this type of process are its simplicity and low preassure drop.

Alternatively, chilling of the gas can be provided by a cascade refrigeration circuit. The refrigerant in this case is either a propane – ethane, a propane – ethylene, or a mixture of propane – ethane – methane – nitrogen (commonly called *mixture refrigerant*). A cascade ethane – propane circuit produces lower temperature than a single propane circuit. Accordingly, the method selected depends on the ethane and LPG recoveries desired. Recoveries of LPG $> 99\,\%$, corresponding to ca. 85 % ethane recovery, are achievable in practice by using mechanical refrigeration. Mechanical refrigeration is more usual in gas processing plants than in refineries because higher LPG recovery is normally required in a gas processing plant to meet the hydrocarbon dew point specification of the sales gas.

A cascade refrigeration plant is illustrated in Figure 4. Impurities such as water, carbon dioxide, and sulfur compounds are removed from the inlet gas, whereupon it is chilled against product gas and external refrigerant. Removal of water and carbon dioxide avoids possible freezing problems in the cold sections of the process. The liquid produced by chilling is fed to the demethanizer, where methane and some ethane are stripped. The vapor separated from separator (i) is used to chill the incoming feed before being commingled with the overhead vapor from the demethanizer. The liquid product from the demethanizer consists of ethane, LPG, and natural gasoline, from which LPG is separated by fractionation. The vapor phase from the demethanizer (mainly methane with some ethane) is heated against the incoming feed before being compressed for sale.

Liquid petroleum gas can also be recovered in a liquefied natural gas (LNG) plant, in which natural gas is fully liquefied by mechanical refrigeration (see Fig. 5). Generally, the external refrigerants employed are propane and a mixed refrigerant consisting of nitrogen – methane – ethane and propane. In the liquefaction process the partially condensed natural gas stream is passed to a distillation column (a) in which ethane, LPG, and the heavier natural gasoline are separated from natural gas. The natural gas (predominantly methane) leaves the distillation column overhead as a vapor product and is subsequently fully liquefied. The liquid phase from the column bottom is routed to a series of fractionation columns for separation into ethane, LPG (individually as propane and butane), and natural gasoline products. Some or all of the ethane and propane products may be used as refrigerants for the LNG plant, with any excess exported.

3.2.2. Expander Plants

Expander plants generate refrigeration by expansion of the feed gas. By dropping the pressure via a contol valve or an expander a sufficiently low temperature can be generated to condense the LPG fraction in the feed gas. The flow scheme for a conventional expander plant is shown in Figure 6.

Treated and dried gas to the plant is first cooled via indirect heat exchange with the cold lean gas exiting the plant (a). Any liquids formed during this first stage of cooling are then recovered in the HP separator (b) and fed to the bottom section of the demethanizer column (e). The overhead vapor from the HP separator is then expanded either via a rotating expander or via a control valve (commonly called a Joule – Thomson valve, d). The cold gas/liquid from the expansion is then fed to the top of the demethanizer. The demethanizer strips the lighter components (methane, nitrogen) from the liquids. The overhead vapor is subsequently fed to the feed gas – gas heat exchanger for recovery of cold before being compressed for export as sales gas. Compression power is minimized by coupling the first stage of the compression to the expander.

A recent development of the conventional expander process has been the gas subcooled process (see Fig. 7). This process is an enhanced expander process in which a rectifying section is added to the demethanizer column. The purpose in adding this section is to reduce the los of ethane and LPG in the overhead vapor by refluxing with cold liquedied feed gas. The reflux is obtained by taking a small portion of the HP separator gas which is then liquefied by chilling against the overhead vapor of the demethanizer.

Figure 5. LPG recovery in an LNG plant
a) Distillation; b) Heat exchanger; c) Demethanizer

Figure 6. Schematic of a conventional expander plant
a) Feed gas – gas heat exchanger; b) HP separator; c) Demethanizer sideboiler; d) Turboexpander; e) Demethanizer; f) 1st Sales gas compressor; g) 2nd Sales gas compressor

The high-pressure cold liquid is then depressurized and fed to the top tray of the demethanizer column. The gas subcooled process is capable of recovering > 99 % of the LPGs in the feed gas and is also ideally suited for recovery of > 95 % of ethane in the feed.

3.2.3. Combined Processes

When high recoveries of LPG and/or ethane are desired, it is possible to assist the conventional expander process with external refrigeration. External propane or cascade refrigeration

Figure 7. Schematic of the gas subcooled process
a) Feed gas – gas heat exchanger; b) HP separator; c) Demethanizer sideboiler; d) Turboexpander; e) Demethanizer; f) 1st Sales gas compressor; g) 2nd Sales gas compressor; h) Reflux exchanger

is applied to cool the feed gas entering the HP separator of the expander plant. The cold gas is then expanded and fed to a conventional demethanizer column.

With this type of process, more than 95 % ethane recovery and essentially 100 % recovery of LPG can be achieved.

3.3. Lean Oil Absorption

The lean oil absorption process employs a hydrocarbon oil to recover light components from either a natural gas or a refinery fuel gas stream. The process is used in refineries worldwide, as well as in natural gas processing plants, especially in the United States, where the vast majority of plants used the oil absorption process until the first expander plant started up in 1963. However, since 1963 expander plants have dominated natural gas processing.

Hydrocarbon oil may be bought in, or components of natural gasoline produced in the gas processing plant may be used. In the refinery, an available fluid such as naphtha is often employed. Despite the different terminology, these streams from the natural gas processing plant and oil refinery are very similar in terms of molecular mass. Typical absorption oils have a molecular mass of 100 – 180.

An example of a refinery lean oil absorption scheme is shown in Figure 8. The fractionator overhead vapor stream is compressed and combined with the liquid top product. The combined stream is then deethanized, and the vapor top product of the deethanizer is brought into contact countercurrently with the absorption oil in the absorber column. The oil absorbs propane and butane components from the gas, replacing them with fewer molecules of the absorber oil. The oil is taken from the main fractionation column (a), presaturated with vapor from the absorber column, chilled to 10 – 15 °C, and fed to the absorber column as lean oil. Presaturation and chilling of the lean oil improve LPG recovery in the absorber. The remaining vapor phase is directed to the fuel gas line. So-called rich oil from the bottom of the column, which contains absorbed LPG is recycled to the main fractionation column to complete the oil circuit. There the LPG is stripped from the rich oil and passed overhead to the deethanizer. The liquid product

from the deethanizer is routed to a fractionation column where the propane and butanes are separated. Typically, LPG recoveries of 85 – 90 % are attainable.

The process applied in natural gas processing plants is, in principle, the same as that used in the refinery, although LPG recoveries of around 98 % are often needed to ensure that gas supplied to the customer satisfies the hydrocarbon dew point specification. This high LPG recovery is achieved by cooling the lean oil to − 40 °C, usually by propane refrigerant. So that the absorber column can operate at this temperature, the natural gas feed must be dried to avoid problems caused by freezing.

3.4. Adsorption

In adsorption (→ Adsorption), gas molecules are reversibly bonded to the surface of a solid material, the adsorbent. Examples of adsorbents include silica gel, activated carbon, and alumina. Adsorption plants are generally used to obtain natural gasolines from natural gas to satisfy sales gas specifications for heavy hydrocarbon content. The LPG recovery is significantly lower than that achieved by refrigeration or lean oil absorption processes. A typical adsorption flow scheme is presented in Figure 9.

Three vessels are shown, each containing the solid adsorbent. The process is cyclical with, at any one time, one vessel on adsorption, one on regeneration cooling, and one on regeneration heating. The inlet gas passes through a bed (a) where heavy hydrocarbons are adsorbed. A slipstream of the inlet gas is compressed and used to cool another bed (b), which has previously been heated to remove adsorbed hydrocarbons. Once this bed is cooled, it is placed on standby ready to be put into adsorption service. Gas leaving this bed (b) is heated to ca. 300 °C in a furnace (e) and directed to another bed (c) to remove adsorbed hydrocarbons. Heavy hydrocarbons present in the regeneration gas leaving this bed (c) are recovered after cooling in a separator (g), from which the remaining gas is returned upstream of the initial bed (a). Liquid removed from the regeneration gas, consisting of natural gasolines and some LPG components, may be processed further by fractionation to yield separate LPG and natural gasoline products.

Whichever method is used to obtain LPG from natural gas or refinery fuel gas, LPG may be produced as a mixed product or as separate propane – propene, called C3 product, and butanes – butenes, called C4 product. The relative quantities of saturated and unsaturated species depend on the types of processes in the refinery that are responsible for LPG production (see Chap. 1). Further fractionation is sometimes employed to recover isobutane from the rest of the C4 product and propene from the C3 product. Isobutane is used in the refinery in the alkylation process, in which it reacts catalytically with either propene or butene to produce high-octane gasoline blendstocks. Propene can also be a valuable chemical feedstock. Thus, depending on the configuration of each refinery, the LPG pool may contain various blends of the saturated and unsaturated components that comprise LPG.

4. Purification

Whether produced in the refinery or a natural gas processing plant, LPG contains contaminants. Most common are water and sulfur compounds, including hydrogen sulfide, carbonyl sulfide, mercaptans, and elemental sulfur. Removal of these contaminants is necessary to satisfy locally applicable quality specifications, for example, DIN 51 622 in the Federal Republic of Germany, BS 4250 in the United Kingdom, and the Gas Processors Association (GPA) specification in the United States. As an example, Table 2 summarizes the requirements for different LPG products according to GPA specifications. Various processes are available to remove contaminants to the prescribed level, some of which are described below.

The first stage of drying LPG is achieved normally by separating *undissolved* water in a coalescer. If the LPG is commercial-grade *butane* which is stored at ambient temperature under its vapor pressure, this is sufficient to meet the water specification. However, if the butane is to be held in refrigerated storage at ambient pressure, further drying is necessary to remove *dissolved* water. This must be performed before the butane is chilled, otherwise problems caused by water freezing will ensue. Water levels in refrigerated LPG are typically less than 10 ppm (mol) to avoid freezing.

Table 2. The LPG specifications of the U.S. Gas Processors Association [6], [7]

Product characteristics	Commercial propane	Commercial butane	Commercial propane – butane mix	Propane HD-5 [a]
Composition	mainly propane and propene	mainly butane and butene	mainly mixes of propane – propene and butane – butene	not less than 90 % propane; not more than 5 % propene
Vapor pressure (max.) at 100 °F, psig [b]	208	70	208	208
Temperature of volatile residue: at 95 % evaporation (max.), °F [b]	− 37	36	36	− 37
Butane and heavier, vol%	2.5			2.5
Pentane and heavier, vol%		2.0	2.0	
Residual matter, residue on evaporation of 100 mL (max.), mL	0.05			0.05
Oil stain observation	pass [c]			pass [c]
Corrosion, copper strip (max.)	no. 1	no. 1	no. 1	no. 1
Volatile sulfur (max.), grains/100 cu ft [e]	15	15	15	10
Moisture content	pass [d]			pass [d]
Free water content		none	none	

[a] HD-5 is the specification of propane for use as automotive fuel. [b] Conversion factors: 208 psig = 1434 kPa (g); 70 psig = 483 kPa (g); − 37 °F = − 38 °C; 36 °F = 2 °C. [c] An acceptable product shall not yield a persistent oil ring when 0.03 mL of solvent residue mixture is added to a filter paper in 0.1 increments and examined in daylight after 2 min as described in test method ASTM D 2158. [d] Passes the GPA Propane Dryness Test (cobalt bromide) or ASTM D 2713-70.

Irrespective of the method of storage, commercial-grade *propane* requires the removal of dissolved water to satisfy the specification.

Adsorptive Purification. Dehydration of LPG can be effected by using a solid adsorbent such as molecular sieve, alumina, silica gel, or calcium chloride. With the exception of calcium chloride, these are regenerative processes operating on a cyclical basis. Dried LPG is taken from the outlet of one of the beds and vaporized by heating. It is then passed through the bed which is to be regenerated, where it heats the bed, thereby desorbing the water. The outlet stream is cooled to condense water and LPG, and the LPG is separated from the water before being returned to the inlet of a bed which is on adsorption service. The regenerated bed is then cooled, filled with LPG, and returned to service, adsorbing water from the LPG.

Molecular sieve units can also handle the combined removal of water, hydrogen sulfide, carbonyl sulfide, and small amounts of mercaptans. Adsorption and regeneration occur in the same manner as for drying only, although water recovered during the regenerative cooling step, as well as the regeneration gas itself, is "sour" (i.e., it contains sulfur compounds) (→ Natural Gas). Molecular sieves tend to be favored when the quantity of contaminant to be removed is small.

Absorptive Purification. The LPG can be brought in contact with an *amine solution* in an absorber column primarily to remove relatively large amounts of hydrogen sulfide. However, amines are not particularly effective for the removal of mercaptans. The sour amine solution is regenerated continuously in a regenerator column at low pressure and high temperature before being recirculated to the absorber column. Amines used include monoethanolamine (MEA), diethanolamine (DEA), and diglycolamine (DGA). Shell's ADIP process employs diisopropanolamine for hydrogen sulfide removal which, with an added downstream mixer–settler system, also allows removal of carbonyl sulfide to low residual levels.

Caustic soda treatment is used primarily to remove mercaptans and smaller quantities (< 100 ppm) of hydrogen sulfide. In an absorber column, LPG is contacted countercurrently with sodium hydroxide solution. The sour caustic solution is then passed to a regenerator column where air stripping oxidizes the mercaptans to disulfides, which are removed from the regenerated sodium hydroxide solution. Regenerated caustic solution is recycled to the absorber. The removal of hydrogen sulfide by sodium hydroxide renders the latter nonregenerable and it must be discarded; hence, bulk hydrogen sulfide removal is normally performed upstream of the caustic unit. Variants of the regenerative caustic process are marketed with additives to enhance the process, for example, UOP's Merox system.

Depending on the type and quantity of contaminants present in the feed and product specifications, one or more of these processes may be employed for LPG treatment. For example, an amine unit for removal of hydrogen and carbonyl sulfides is frequently present in the refinery, followed by a caustic unit to remove the remaining hydrogen sulfide and mercaptans before final product drying with alumina (see Fig. 10). However, in case of particularly severe product specifications (e.g., if the LPG is used as chemical feedstock), further treatment may be necessary to remove carbonyl sulfide and mercaptans to very low levels. A "polishing" step is then incorporated, generally using adsorbents on a nonregenerative basis (e.g., Selexsorb).

5. Storage and Transportation

The storage of LPG may be categorized as follows: pressurized storage at ambient temperature; refrigerated storage at ambient pressure; and semirefrigerated, partially pressurized product storage. Further, LPG may be stored either above or below ground.

Aboveground Storage. The design pressure of aboveground *pressure storage* tanks is normally 1724 kPa for propane vessels and 860 kPa for butane vessels. These values correspond to the vapor pressures of both compounds at the maximum expected ambient temperature. For smaller inventories (up to ca. 100 t), the vessels are usually horizontally or vertically mounted cylinders with hemispherical heads. Larger inventories tend to be stored in spherical vessels.

The largest pressurized spheres hold ca. 1500 t; thus, for storage of larger quantities than

Figure 10. Refinery LPG product treating
a) Amine treatment; b) Caustic treatment; c) Drier; d) Polishing

this, either several spheres are needed or *refrigerated storage* must be used. This is designed to store the LPG product at its atmospheric boiling temperature (i.e., ca. $-42\,°C$ for propane and $-4\,°C$ for butane). The tank design pressure is typically ca. 110 kPa. Tanks are insulated; vapors liberated by heat leaking in are compressed, liquefied, and returned to the storage tank. Usually, the boil-off vapor is liquefied by the refrigeration system provided to chill the LPG product rundown from the producing plant. Sometimes, the aboveground storage facility is mounded with earth, as can be seen in Figure 11, which shows two 50 000-m^3 and two 35 000-m^3 tanks.

Figure 11. Fully refrigerated, mounded LPG storage tanks

Semirefrigerated storage can also be used: propane is stored at $-10\,°C$, at which its vapor pressure is ca. 320 kPa.

Underground Storage. The LPG may also be stored underground in salt or quarried caverns that can withstand its vapor pressure at subterranean temperature. These have been used in the United States, Canada, and Europe. In frozen-earth storage, the ground surrounding the excavation is frozen and an insulated roof is constructed over the cavity. Propane is more suitable for storing by this method because its boiling point at atmospheric pressure is considerably lower than the freezing temperature of the soil thus causing moisture in the soil to freeze. Refrigerated propane product at ca. $-42\,°C$ is loaded into the cavity where it is held at atmospheric pressure. Propane vapors liberated by heat leaking in are compressed, cooled, and returned to the cavity storage as liquid.

Transportation. Depending on the location of LPG-producing plants in relation to markets, LPG may be transported by pipeline, sea, road, or rail. Traditionally, LPG has been carried in pressurized ships as well as trucks and rail cars, except for bulk refrigerated deliveries to Japan. Pipelines have been used for inland transportation of large volumes, particularly in the United States. For transport to the consumer, LPG is delivered in cylinders and bulk vehicles of various sizes. The maximum capacity of a *pressurized* LPG ship is limited to about 2000 m^3 due to high manufacturing costs. *Semirefrigerated* ships usually hold 2500 – 5000 m^3, with *fully* refrigerated ships having capacities up to 100 000 m^3. The larger the LPG cargo, the more economical it is to transport fully refrigerated.

The LPG can be unloaded into refrigerated storage tanks or, after heating, into pressurized tanks which supply conventional pressurized distribution facilities. Alternatively, cargo may be transferred into smaller coastal tankers for delivery of refrigerated products to smaller terminals which cannot receive large oceangoing ships. In Figure 12 a fully refrigerated LPG ship is seen at a loading jetty.

6. Uses

The LPG supplied in cylinders or delivered to larger bulk tanks finds a market in domestic, commercial, and industrial sectors. In the domestic and commercial markets, LPG provides a clean fuel for cooking, heating, and automobiles. It is an especially attractive automotive fuel because it substantially lowers vehicle exhaust emissions. In the industrial market, LPG is suitable for many uses where high-quality fuel is required. The high costs of storage and handling normally limit LPG to those applications in which it can command a premium price.

Significant quantities of LPG are also used in the refining and petroleum industries. In the refinery, butane is used primarily in the production of gasoline; *n*-butane is added to increase the volatility and octane number of the fuel, whereas isobutane and butene are consumed by the alkylation process to provide high-octane alkylates for gasoline blending (→ Oil Refining). An important use of LPG as a chemical feedstock is in the manufacture of intermediates for polymers such as polyethylene, poly(vinyl chloride), and polypropylene, to name a few.

In the *pipeline gas industry*, LPG may be used in various ways. Propane can be injected close to the consumer when the pipeline is overloaded or, less often, earlier in the transmission system when there is a shortage of gas. Because of the effect on the calorific value and burning characteristics of the gas, the quantities of propane that may be used are limited. Alternatively, an air – propane mixture may be introduced in larger quantities, and this method of increasing gas supplies during peak demand periods has been employed for many years. Butane is not as attractive for this service because of its higher boiling point.

7. Safety Aspects

Throughout the process of LPG manufacture, storage, transportation, and consumption, high safety standards are necessary because LPG is a hazardous substance. It is flammable and, in the event of leakage, can release large amounts of flammable gas which may migrate considerable distances from the source of the leak before being ignited. Being heavier than air, escaping LPG readily accumulates at low points, including open and closed drains and sewers.

Generally, precautions must be taken to minimize the likelihood of uncontrolled leakage and eliminate ignition sources. When controlled leakage of LPG from storage or plant has to be allowed for, it must be piped to a safe location for disposal in a controlled manner, normally by flaring. To this end, equipment used in the storage and processing of LPG is fabricated according to procedures laid down in the appropriate codes. These specify, for example, construction materials; required wall thickness; inspection requirements; and protective devices such as safety relief valves, depressurizing facilities, water deluge systems, and emergency shutdown valves. Ignition sources are also kept out of plant or storage areas where the risk of LPG release exists. Accumulation of static electricity is prevented by ensuring that all equipment is earthed.

Occupational Health. LPG is an asphyxiant, causing suffocation by the exclusion of an oxygen atmosphere. It is, however, not a toxic substance. The precautions required center on making sure that people are not exposed to a suffocating atmosphere. For example on a manufacturing plant personnel must not enter a vessel unless that vessel is suitable for entry, i.e., it has been physically disconnected from other plant equipment and freed of flammable substances by purging with inert gas (normally nitrogen) followed by replacement of the inert gas with a breathable oxygen atmosphere.

8. Economic Aspects [8], [9]

The major producers and exporters of LPG are the Middle East, Canada, North Africa, and the

Figure 12. Refrigerated LPG ship

Far East. Reduced flaring of natural gas, particularly in the Middle East, is expected to contribute significantly to the quantities of LPG available for export. Prospects for international trade are also improved by the reduction in freight costs associated with the use of large-capacity refrigerated LPG ships.

The total world consumption of LPG in 1993 was 159×10^6 t, the main consumers being the United States, Japan, and Western Europe.

United States. In the United States, consumption in 1993 totaled 84×10^6 t. Historically, ca. 70 % of the LPG production in the United States has been supplied by gas processing plants, with oil refineries providing the remaining 30 %. The volumes produced internally have not quite satisfied local demand; therefore, some imports (ca. 10 % of the total demand) have been necessary. Most of the imports have come from Canada and the Middle East. Future production of LPG from natural gas is predicted to decrease as greater proportions of the gas are taken from wells containing less LPG. Consequently, LPG imports are expected to increase in the United States.

Japan. In 1993, LPG consumption in Japan was 20×10^6 t. Japan has little indigenous natural gas, which strongly influences the LPG market. The lack of natural gas has resulted in a public gas distribution system which is less extensive than in other industrialized countries. Consequently, on the demand side, the market for LPG is large with two-thirds of the total demand typically being from the domestic and industrial sectors. Another important feature of the Japanese market is the demand for clean burning fuels, for example, in the automotive and power generation sectors. On the supply side, the lack of natural gas means that the only sources of LPG produced locally are oil refineries. The LPG produced by refineries is insufficient to meet the demand, to such an extent that Japan was the largest single importer of LPG in 1993, importing 15×10^6 t.

Western Europe. In Western Europe, LPG consumption was 32×10^6 t in 1993. Traditionally, the LPG supply in Europe has come from refinery production, to a market restricted to some extent by the availability of pipeline natural gas. However, by the early 1980s increased demand had led to most Western European countries becoming net importers. In 1983 this was still true, although in the United Kingdom exports and imports were finely balanced because of the LPG produced from the British sector of the North Sea.

1. Introduction

For a century, compounds have been recognized which, on melting or addition of a solvent, pass through phases that have a degree of order lower than the crystalline solid, but higher than the normal isotropic liquid [7]. Compounds containing rod- or disk-shaped molecules frequently pass through such intermediate phases, termed *mesophases*, in which the molecules are free to move past each other but are aligned parallel to one another within macroscopic volumes of the fluid. Such materials are known as liquid crystals because they combine in a single phase the typical flow of a liquid with the anisotropy of properties found in noncubic crystals. All liquid crystal phases share this orientational order; different liquid crystal phases are distinguished by varying degrees of additional order.

Liquid crystal phases have been discovered in a great range of organic chemicals [8], including cellulose derivatives, peptides, surfactant systems, drugs, and dyes. Stimulus for the development of liquid crystals has, however, come largely from the discovery of electro-optic effects in a restricted range of liquid crystal phases and their exploitation in displays (→ Display Technology). This article reflects that emphasis and describes the technologically important liquid crystal phases in some detail, while providing a briefer account of other areas of liquid crystal science.

2. Classification and Nomenclature of Liquid Crystal Phases

The wide variety of chemical systems and phase types encompassed by the term liquid crystal has led to the use of a number of specific terms in the literature. Compounds which form liquid crystal phases are often termed *mesogens*. Liquid crystals formed on heating a crystalline solid are referred to as *thermotropic phases*. Such phases may also be obtained on supercooling an isotropic liquid below the melting point of the crystalline solid and are then described as *monotropic phases*. Monotropic transition temperatures are conventionally cited in parentheses. *Enantiotropic phases* exist as the thermodynamically stable phase between the crystalline

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_359

melting point and the *clearing point* (the temperature at which the liquid becomes clear due to a reversible transition to the isotropic state). In some cases a liquid crystal phase cannot be observed in a compound due to its failure to supercool adequately, but the properties of a *virtual liquid crystal phase* can be inferred from the behavior of the compound in solution in a liquid crystal solvent. Virtual transition temperatures are conventionally cited in square brackets.

Liquid crystalline behavior has been most thoroughly explored in compounds composed of rod- or lath-shaped molecules which form *calamitic phases*. This distinguishes them from the *discotic phases* formed by flat plate- or disk-like molecules. Calamitic liquid crystal materials form *nematic phases* having only orientational order, *cholesteric* or *chiral nematic phases* which have only a helical orientational ordering, and *smectic phases* in which statistically parallel molecules are arranged in layers. Discotic liquid crystals also form nematic and chiral nematic phases, as well as *columnar phases*: in the latter, disk-shaped molecules stack together to form rodlike entities.

Lyotropic liquid crystal phases are formed on addition of a solvent to a solid compound: lyotropic nematic, cholesteric, and smectic phases are known.

Both thermotropic and lyotropic *liquid crystal polymers* are known: such polymers may contain discotic or calamitic liquid crystal subunits in the main chain, as pendant groups, or in combination.

In addition to the common categories outlined above, less common liquid crystal phases occur. *Bowlic phases* derived from dome-shaped molecules have been discussed in the literature; *biaxial nematic phases* have been described [9–11], and new phases are sometimes named after the classes of compounds exhibiting them. In view of the rapid progress in liquid crystal science the reader must be prepared for the emergence of new phases and phenomena, with nomenclature to match.

3. Thermotropic Calamitic Phases

Liquid crystal phases derived from rodlike molecules form the best studied category of mesophases. The first liquid crystal material studied, cholesteryl benzoate (**1**) [*604-32-0*],

1

forms phases of this type. The relatively common occurrence of liquid crystal phases in, and ease of synthesis of, compounds in which two or more aromatic rings carrying terminal groups (**2**) are

2

linked together led to these systems forming the exemplary phases on which liquid crystal science is based. A selection of compounds forming thermotropic calamitic phases is given in Table 1.

3.1. Thermotropic Liquid Crystal Polymorphism

Liquid crystal phases share the property of orientational ordering of anisotropic molecules, but a number of phases can be distinguished in which additional degrees of positional or orientational order exist [12]. The crystalline phase is designated as K and the isotropic liquid as I. The *nematic phase* (N), which usually forms a fluid of low viscosity, exhibits only long-range orientational order (Fig. 1 A). The long axes of the molecules tend to align parallel within macroscopic volumes of liquid.

Smectic phases (S), in which the molecules are additionally ordered in layers, form a range of very viscous fluids or waxy solidlike materials [13]. The least ordered smectic phase, denoted *smectic A* (S_A), has disordered layers in which the molecules can move freely in two dimensions (Fig. 1 B). Motion in the third dimension would imply hopping between layers and is restricted by an energy barrier. In the S_A phase, the average orientation of the molecular long axes is perpendicular to the layer planes, but this phase is subject to the same thermal disordering as the nematic phase. A corresponding phase in which

* K = crystalline phase; S = smectic phase; N = nematic phase; I = isotropic liquid.

Figure 1. Schematic representation of molecular arrangement in the nematic (A), smectic A (B), and smectic C (C) phases

the molecules are tilted in the layers is known as the *smectic C phase* (S_C). The direction of molecular tilt is correlated between layers, and the S_C phase is formally biaxial (Fig. 1 C). Several subdivisions of S_A and S_C phases have been characterized.

In compounds and mixtures which exhibit liquid crystalline polymorphism, smectic phases usually occur at lower temperature than the less ordered nematic phase, but many exceptions to this rule are encountered. For example, the 4′-cyanobiphenyl ester of 4-(octyloxy)benzoic acid (**13**) [*61195-44-6*] shows the phase transition

13

sequence K 97 N 120 S_A 201 N 240 I (the numbers indicate the phase transition temperature in degrees Celsius), thereby indicating a smectic phase that can be transformed to a nematic phase either by heating or by cooling. Examples of such *reentrant phase sequences* involving S_A and S_C phases are particularly common in compounds containing dipolar linking groups and terminal cyano or nitro groups.

Three phases exist in which hexatic (short-range hexagonal) molecular ordering exists in the layers (Fig. 2). In the hexatic smectic B phase (S_B^H) the molecules are statistically perpendicular to the layer planes and free to rotate about their long axes. There is, however, a short-range positional ordering of the molecules on a hexagonal net which possesses long range orientational order. The smectic I and F phases are tilted analogues of the hexatic B phase, in which the molecular tilt is directed toward either an apex or a face of the hexagonal net, respectively.

Strictly speaking, the remaining smectic phases (D, E, G, H, J, K) should not be regarded as liquid crystals; they possess three-dimensional long-range order and are more correctly classified as disordered solids. The crystal B phase (S_B^{Cr}) has true long-range order on a hexagonal net in each layer, with correlation of molecular position between layers. The tilted phases with three-dimensional ordering that correspond to the smectic I and F phases are denoted J and G, respectively. Finally, smectic phases are observed in which loss of complete rotational freedom of molecules about their long axes occurs. In these phases the molecules adopt a herringbone packing. An orthogonal phase (S_E) and tilted phases (S_K, S_H) are known. The smectic D phase occurs rarely, and its structure has not been elucidated fully but is based on a primitive cubic lattice. Other similar, but apparently distinct, cubic phases have been observed.

The identification and classification of liquid crystal phases rests on three techniques. Many phases show characteristic appearances (textures) when observed in a thin film in a polarizing microscope [13]. These textures are often sufficient to identify phases, especially when use is made of the known relative thermal stability of smectic phases [14]. When the sample temperature decreases, phases occur in a set order by selection from the sequence S_A, S_D, S_C, S_B^H, S_I, S_F, S_B^{Cr}, S_J, S_G, S_E. In case of doubt, recourse may be made to testing the miscibility of a phase with a known standard material. Miscibility over the complete composition range implies identity of the phases; however, different phases may also mix over all but a narrow region of the phase diagram, and phases of identical symmetry can fail to mix. Final clarification of a phase structure may be obtained by X-ray studies.

Figure 2. The hexagonal local order found in certain smectic liquid crystal phases
The molecules may be orthogonal to the layers [(A); S_B^H and S_B^{Cr}] or tilted toward a face [(B); S_F and S_G] or apex [(C); S_I and S_H] of the hexagonal net. In the hexatic phases, S_B^H, S_F and S_I, the positional order is short-range but the orientation of the hexatic net is maintained over long ranges. There is no correlation of molecular position between layers. In the crystal smectic S_B^{Cr}, S_G, and S_H phases the molecules lie on a lattice with long-range positional order in each layer. The molecular positions are also correlated between layers.

3.2. Structure – Phase Relationships

No predictively useful theory is available to relate molecular structure to liquid crystal phase type and stability, but experience accumulated over the past century has led to a number of useful empirical rules. Experienced workers can frequently predict liquid crystal phase stability and clearing points for novel systems by reference to analogous known materials. Prediction of phase type, particularly between smectic polymorphs, is much more difficult.

Relative ease of synthesis means that aromatic systems have been most extensively explored as liquid crystals. A very wide range of compounds conforming to structure **2** are known. At least two ring structures are normally necessary to stabilize a calamitic liquid crystal phase. The apparent contradiction of this principle by compounds such as 4-pentylbenzoic acid (**14**)

14
K 88 N 126.5 I

[*26311-45-5*], is explained by dimer formation, but a few genuinely acyclic mesogens are known e.g., *E,E*-2,4-undecadienoic acid (**15**) [*74267-92-8*].

15
K 32 N 62.5 I

The central features of liquid crystalline compounds conforming to structure **2** include an elongated rigid molecular core substituted with terminal groups, which may be flexible or polar, and a high anisotropy of electric polarizability. The nature of the terminal groups can strongly affect the stability of the liquid crystal phases, and groups that extend the electronic conjugation of the core increase the transition temperature. An order may be compiled for the efficiency of terminal groups in promoting nematic phase stability:

$$C_6H_5 > CN > OCH_3 > NO_2 > Cl > CH_3 > F > CF_3 > H$$

On ascending a homologous series of mesogens, an alternation in transition temperatures is frequently observed. Odd-carbon alkyl chains give higher clearing points than even-carbon alkyl chains (e.g., $C_3H_7 > C_4H_9$); even-carbon alkoxy groups give higher clearing points than odd-carbon ones (e.g., $OC_2H_5 > OC_3H_7$). The underlying trend in clearing points varies with the nature of the molecular core: clearing points may rise gradually, rise initially and then fall, or fall initially and then rise. The temperature range of the liquid crystal phase is often largely

determined by the effect of terminal groups on the melting point of the system. In most homologous series, a nematic phase predominates in short-chain compounds and smectic phases are introduced in the higher homologues, with eventual exclusion of the nematic phase.

The central linking group in structure **2** also has an important effect on liquid crystal phase stability; a group that extends electronic conjugation between the rings significantly increases the clearing point. The group must also retain the rigidity and linearity of the core structure. Suitable linking groups include:

Groups having a poor effect on liquid crystal phase stability within this environment include:

The central linking group was a frequent source of hydrolytic or photolytic instability in early liquid crystals used at room temperature. Exploitation of a single bond as a linking group led to the discovery of the cyanobiphenyls as the first highly stable room temperature nematic liquid crystals.

Early observations relating structure to phase stability, together with the success of the Maier–Saupe theory of nematic ordering (see Section 3.3) supported the view that electronic polarizability was an important contributor to liquid crystal phase stability. This theory was reinforced by the early synthesis of alicyclic systems with poor liquid crystal properties (cf. **16** [*1818-98-0*], **17**) but had long been contradicted

16
K 153 N 241 I

17
K 129 N 157 I

by the mesogenic properties of a range of derivatives of cholesterol and other sterols. Subsequent synthesis of structures in which replacement of an aromatic ring by an alicyclic ring improved liquid crystal stability, led to an appreciation of the true situation [15]: alicyclic ring structures form good structural units for liquid crystal molecules, but regions of high polarizability or polarity must not be separated by a linking group of low polarizability. These points are well illustrated by the N–I transition temperatures of the following sequence of compounds:

6
N 35 I

4′-pentylbiphenyl-4-carbonitrile [*40817-08-1*]

18
N–25 I

4-(pentylphenyl)cyclohexanecarbonitrile [*66227-29-0*]

19
N 55 I

4-(4-pentylcyclohexyl)-benzonitrile (PCH5) [*62788-05-0*]

20
N 85 I

trans, trans-4-pentyl-1,1′-bicyclohexyl-4-carbonitrile (CCH5) [*77449-35-5*]

Another dramatic example is provided by the reversal of the linking group in compounds **21** and **22**:

21
N 33.5 I

1-[(4-methylphenoxy)methyl]-4-pentylbicyclo(2.2.2)octane [*81472-49-3*]

22
N–210 I

1-[(4-methylphenyl)methoxy]-4-pentylbicyclo(2.2.2)octane [*97129-82-3*]

However, the effect of isolating an ether group is not always as striking; for example, in the phenyldioxane derivatives the N – I transition temperatures are similar to those of their cyclohexane analogues–cf. **19** above and 4-(5-pentyl-1,3-dioxan-2-yl)benzonitrile (**23**) [*74800-62-7*].

23
K 56 N (52) I

Subject to these restrictions, aromatic, alicyclic, and heterocyclic structures can be combined in liquid crystal molecules. The linearity of mesogenic molecules is compromised by lateral substitution. Large groups at the side of the molecule greatly lower the clearing point; smaller substituents have less effect. Fluorine occupies a unique position in that it substantially modifies the nature of the liquid crystal phase, while retaining a clearing point which is only modestly reduced relative to the unsubstituted parent compound. A lateral fluorine with the ring-fluorine bond directed toward the center of the molecule usually destabilizes smectic phases in favor of the nematic. Smectic phases are more likely to be tilted in the presence of such a substituent. When the ring-fluorine bond is directed away from the molecular core, however, smectic phase stability is little affected or enhanced. Halogens other than fluorine, together with short-chain alkyl groups, etc. give similar results, but with a much greater effect on the clearing point.

Compounds without strongly polar groups frequently show smectic phases over a wide temperature range. A nematic phase may then be introduced or extended by introduction of a polar group or by lateral substitution:

5-hexyl-2-[4-(hexyloxyl)phenyl]pyrimidine (PYP 606) [*51518-75-3*]

The choice of linking groups is important in determining smectic polymorphism. Schiff bases are frequently richer in smectic phases than their equivalent esters. Chain branching can also enhance smectic polymorphism, as well as lowering clearing points. An example of the effect of chain branching is demonstrated by

(±)-4′-octyl biphenyl-4-carboxylic acid, 4-(2-methylbutyl) phenyl ester (**30**) [*66424-45-1*]:

Smectic phases often predominate in liquid crystal materials having terminal dipoles with a strong component perpendicular to the molecular long axis. Examples are demonstrated by the hexyl ester of 4′-(decyloxy biphenyl)-4-carboxylic acid (**31**) [*62724-39-4*] and 1-(4′-methoxy biphenyl-4-yl)-1-pentanone (**32**).

This brief discussion shows that rather subtle changes of molecular structure can have a radical effect on liquid crystal phase behavior. The existing basic knowledge of structure – property relations is adequate only when closely related materials are considered. This important area is the subject of review articles [15–17].

3.3. The Nematic Phase

The nematic phase is the least ordered of the liquid crystal phases, the molecules having their long axes arranged statistically parallel over large distances in the fluid (Fig. 1 A). The molecules do not have any positional order and can rotate freely about their long axes. Liquid crystal molecules with different terminal groups have no ordering of their disposition; that is, rotation of any molecule through 180° about its short axis leaves it in a state of the same energy. A vector drawn parallel to the preferred orientation direction of the molecular long axes is referred to as the *director*.

Although the molecules of a nematic liquid crystal align parallel to one another on average, considerable disorder occurs in this orientation in all real liquid crystal phases. This leads to the definition of an *order parameter* with the following properties:

1) The order parameter of the isotropic liquid is 0.
2) The (hypothetical) perfectly ordered liquid crystal with all molecular long axes parallel has an order parameter of 1.
3) The order parameter has the same symmetry properties as the nematic phase. In particular, the order parameter is unchanged if any molecule is rotated through 180° or if the angle it makes with the director is reversed.

The simplest, most commonly used order parameter is

$$S = 1/2\langle 3\cos^2\theta - 1\rangle$$

where θ is the angle between each long molecular axis and the director, and the angle brackets imply an average over a large number of molecules.

The Maier – Saupe theory of nematic ordering [18], [19] achieves semiquantitative agreement with experimental results when liquid crystal molecules are presumed to interact only via electrostatic dispersion forces. At first sight the approximations made in this approach appear unreasonable; in practice the neglected forces apparently make a large but almost isotropic contribution to the intermolecular potential and are not decisive in determining the stability of a liquid crystal phase [20]. The Maier – Saupe theory predicts that the order parameter decreases with increasing temperature T, but retains a finite value of ca. 0.42 at the nematic – isotropic transition $T_{\mathrm{N-I}}$, at which point it falls discontinuously to zero. The behavior may be approximated [4] by the equation

$$S \approx (1 - 0.98T/T_{\mathrm{N-I}})^{0.22}$$

where T is the absolute temperature.

An alternative approach to understanding the properties of the nematic phase is that of Onsager [6]. This theory seeks to avoid the worst assumptions of the Maier – Saupe approach by ascribing liquid crystalline ordering to repulsive interactions between molecules. Considering only these short-range forces, the Onsager

approach does not agree well with experimental results in regard to either S or density change at the clearing point.

Several attempts have been made to include both attractive and repulsive forces in a theory of nematic ordering, and computer simulations using increasingly realistic interaction potentials are now possible [21]. Even the most complex current calculations, however, fail to provide real insight into the changing liquid crystal behavior observed as molecular architecture is altered.

3.4. Physical Properties of Nematic Liquid Crystals

The static physical properties of liquid crystal materials resemble those of other organic liquids, but liquid crystal phases commonly show anisotropy in their properties [4], [22]; i.e., the magnitude of each physical property varies according to the relative geometry of the sample and the measuring equipment. Nematic liquid crystals are uniaxial, and each property is characterized by two principal values measured with the probe field parallel ($\|$) and perpendicular ($\perp$) to the director. The anisotropy of the physical property is defined as the difference between these two values.

3.4.1. Refractive Indices

The refractive indices (n) of nematic liquid crystals can be measured in a conventional instrument such as an Abbe refractometer with the director perpendicular to the direction of propagation of the light beam (Fig. 3). Such a sample geometry may be maintained by surface forces (see below). Under these circumstances an incident light beam is split into an ordinary and an extraordinary ray that are polarized perpendicular and parallel to the nematic director, respectively: these two rays are deflected through different angles appropriate to the corresponding principal refractive indices (n_0 and n_e) of the liquid crystal. Nematic liquid crystals are positive uniaxial crystals; i.e., $n_e > n_0$ and the birefringence Δn is positive:

$$\Delta n = n_e - n_0 > 0$$

On a molecular level, the refractive index of an organic medium is determined by the electronic polarizability. For a nematic liquid crystal, the polarizability both parallel and perpendicular to the molecular long axis must be considered. The contribution each molecule makes to the refractive indices of the phase is modified by the angle it makes to the director and thus to the order parameter. Rigorous interpretation of refractive index data is complicated by the anisotropy of the environment of each molecule. An extension of the Lorentz approach [4–6] leads to the prediction

$$\frac{n_e^2 - n_0^2}{\bar{n}^2 - 1} \sim S \tag{1}$$

$$\bar{n}^2 = \left(2n_e^2 + n_0^2\right)/3 \tag{2}$$

and is justified by the observation that the left hand side of Equation (1) is indeed closely proportional to S measured by independent means. The refractive indices of a nematic liquid crystal provide a means of measuring the order parameter S: Equation (1) is applicable if S can be obtained at a single temperature. Haller made the reasonable assumption that S tends to unity at zero Kelvin, and found [23] that linear extrapolation of refractive index data to this temperature was available from a plot (Fig. 4) of

$$\log\left(1 - T/T_{N-I}\right) \text{ vs. } \log\left[\left(n_e^2 - n_0^2\right)/\left(\bar{n}^2 - 1\right)\right] \tag{3}$$

This extrapolation therefore allows the proportionality constant of Equation (1) to be determined from refractive index measurements conducted at accessible temperatures. The constant number determined may be reapplied to the same data to obtain a value for S at each temperature of measurement. The denominator in the second expression of Equation (3) allows for the variation in density with temperature. Figure 5 shows the order function S as a function of temperature. For most applications, the birefringence of a nematic liquid crystal is the most important optical property because it defines the strength of interaction between the liquid crystal and light. Higher birefringence is observed in aromatic liquid crystals than in alicyclic ones and is further increased by π-bonded linking and terminal groups conjugated with the aromatic rings (Table 2). Birefringence

also increases in materials in which the clearing temperature is much higher than the measurement temperature. When low absolute refractive indices are required, suitable materials can be obtained by combining alicyclic liquid crystals with isotropic fluorinated dopants such as $C_7H_{15}CO_2CH_2(CF_2)_{10}H$ [24].

3.4.2. Dielectric Constants

The anisotropy of dielectric constants in the nematic liquid crystal phase mirrors that of the refractive indices; each material is characterized by two principal values parallel and normal to the director, denoted $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$, respectively. The Maier and Meier treatment of liquid crystal dielectric constants considers both the polarizability anisotropy of molecules $\Delta\alpha$ and a permanent dipole moment μ at an angle β to the long molecular axis [25]. As in the treatment of refractive indices, the internal field must be estimated, and the environment of the molecule is therefore assumed to be isotropic. The dielectric anisotropy obtained is

$$\Delta\varepsilon = \left[A \cdot \Delta\alpha - \frac{B\mu^2}{T}\left(1 - 3\cos^2\beta\right)\right] S \qquad (4)$$

where A and B are material-dependent constants. Although this expression has predictive usefulness for correlation of material properties with molecular structure, it fails to account for all the observed dielectric properties of liquid crystals. For a suitable value of β (ca. 55°), the second term in square brackets becomes zero, and any molecular dipole moment at this angle makes no contribution to the dielectric anisotropy. The result is a small positive dielectric anisotropy due to the positive polarizability anisotropy. Many liquid crystal molecules used in practice possess strong dipole moments almost parallel to the long molecular axis, produced by terminal substituents such as −CN and −NCS groups. In these cases, $\beta = 0$ and the positive dipolar term commonly dominates the polarizability in terms of their relative contribution to $\Delta\varepsilon$. Despite this, the dielectric anisotropy observed in terminal dipolar compounds is frequently much smaller (e.g., by a factor of two) than implied by Equation (4). Evidence has become compelling that a local antiparallel ordering of the dipole moments in these systems reduces their effective magnitude and their influence on dielectric properties [12], [26]. The degree of antiparallel correlation is a function of molecular structure and temperature, and depends on the composition of mixtures of liquid crystal materials. Consequently, the magnitude of this important effect cannot be predicted accurately. In a few cases, most notably esters, of the type **35**, the evidence indicates that a predominantly

35

parallel ordering of the molecular dipoles exists [27]; these compounds are characterized by very high values of positive dielectric anisotropy. When the molecule has a lateral dipole, β is

Table 2. Birefringence and chemical structure of nematic liquid crystals

greater than 55° and the dipolar contribution to $\Delta\varepsilon$ is negative. However, even when $\beta = 90°$, a lateral dipole moment is only one-half as effective in inducing a negative $\Delta\varepsilon$ as an axial dipole is in inducing a positive one. Design and synthesis of liquid crystals with a very high negative dielectric anisotropy is difficult, the problems being compounded by the tendency of lateral substituent groups to distort the rodlike form of the liquid crystal molecule and adversely affect the thermal stability of the mesophases. Nevertheless, liquid crystal materials with a wide range of dielectric properties can be obtained by suitable selection of dipolar substituents (Table 3).

Dielectric relaxation leads to a change in the effective dielectric constant as the frequency is raised through a range where the molecular dipole can no longer contribute fully to the molecular response to a field. The relaxation commonly encountered reduces $\varepsilon_{\parallel}$ in a temperature- and material-dependent frequency range in the kilo- or megahertz region. The effect can be exploited to provide liquid crystal materials that have positive dielectric anisotropy at low frequencies but negative anisotropy above a crossover frequency [28]. Use of these two-frequency materials in display applications has been discussed but has never been widespread.

Figure 5. Order parameter vs. temperature for nematic mixture E7

3.4.3. Diamagnetic Constants

Common liquid crystal materials are diamagnetic and show a corresponding diamagnetic anisotropy $\Delta\chi$, which behaves in an analogous way to the dielectric anisotropy $\Delta\varepsilon$. The weak interaction of most liquid crystals with a magnetic field means that the effect is rarely used in practical applications. However, it is important to physicists because the small magnitude of the diamagnetic susceptibility means that the internal field problems relevant to dielectric properties do not arise and the theoretical treatment of

data is on a sure footing [5], [6]. Diamagnetic measurements are frequently used for the evaluation of order parameters:

$$S \sim \Delta\chi = (\chi_{\parallel} - \chi_{\perp})$$
$$\bar{\chi} = (\chi_{\parallel} + 2\chi_{\perp})/3$$

where $\chi_{\parallel}$ and $\chi_{\perp}$ are the diamagnetic susceptibilities measured with the magnetic field parallel and perpendicular to the nematic director, respectively. As in the case of order parameter measurements by using refractive index data (Section 3.4.1), an independent method is needed to establish the proportionality constant between S and $\Delta\chi$.

Most liquid crystal materials have a positive diamagnetic anisotropy; the 4-alkyl-4′-cyanobicyclohexanes (**21**) form a notable exception. The lack of practical applications means that little systematic optimization of diamagnetic properties has been attempted. Paramagnetic liquid crystals are known, but the anisotropy is apparently small [29].

3.4.4. Elastic Constants

Liquid crystals are unique among fluids in their elastic behavior. Although the definition of a fluid precludes the possibility of a static shear stress being sustained, a nematic liquid crystal can transmit a torque stress. The treatment of nematic liquid crystal elasticity elaborated by FRANK is based on the concept of a torque stress resulting in a corresponding strain [2–6]. Proportionality between stress and strain is assumed to hold for small deformations and is mediated by curvature elastic constants k having the units of force. All deformations of a liquid crystal sample can be expressed as a sum of three elementary distortions denoted splay, twist, and

bend. These distortions are opposed by the corresponding elastic constants k_{11}, k_{22}, and k_{33} (or k_1, k_2, and k_3, respectively) (Fig. 6). The elastic constants are of the order 10^{-11} N, leading to an elastic behavior considerably weaker than that observed in solids. Although the effect of the elastic constants can be detected, and their magnitude measured by standard means such as a torsion balance, a more convenient experimental technique is the observation of a Frederiks transition in a liquid crystal sample under an applied magnetic or electric field (see Section 3.5.1). For many samples, $k_{11} \approx k_{33} \approx 2\,k_{22}$

Figure 6. Elementary distortions of nematic liquid crystals

No satisfactory theory exists for predicting elastic constants from molecular structure. Information has been obtained by systematic measurement of a range of compounds, which allows an incomplete set of structural correlations to be formulated [30–34]. The ratio k_{33}/k_{11} is used most frequently as a measure of elastic properties both because of the body of data available and because it is important in determining the behavior of nematic liquid crystals in some practical applications. In molecules with long terminal alkyl substituents, k_{33}/k_{11} decreases. Terminal short chains and alkoxy substitution increase k_{33}/k_{11}. By contrast, evidence suggests that increasing the length : breadth ratio of the rigid core of liquid crystal molecule raises k_{33}/k_{11}. Aromatic and heterocyclic systems have lower k_{33}/k_{11} ratios than the corresponding alicyclic derivatives. The theoretical prediction that k_{ii} is proportional to S^2 is realized only approximately in practice. The proximity of a smectic phase alters the short-range order in a nematic liquid crystal and frequently reduces k_{33}/k_{11} [35–38]. Closer to an underlying smectic phase, a pretransitional increase in elastic constants is observed, especially k_{22} and k_{33}.

3.4.5. Light Scattering

An important consequence of the small magnitude of the elastic constants is that fluctuations in director orientation require little energy and can be thermally driven [5]. Such thermal fluctuations lead to changes in the effective refractive index experienced by a light beam propagating in the nematic liquid crystal. Fluctuations that occur at a short wavelength, comparable with the wavelength of light, lead to light scattering and opacity in the sample. Light scattering from nematic liquid crystals is several orders of magnitude stronger than from isotropic liquids and leads to the common description of the liquid crystal-to-isotropic transition temperature as the clearing point.

3.4.6. Viscosities

The viscous flow of nematic liquid crystals is complicated by two factors [4–6], namely, the anisotropy of the viscosities and the tendency for shear stress to rotate the director orientation in the sample and modify the experiment. Five independent viscosities are required to characterize a nematic liquid crystal fully; of these the three Miesowicz viscosities ($\eta_1 - \eta_3$) are the anisotropic analogues of ordinary fluid viscosities. The relative dispositions of the director and shear gradient allowing measurement of the Miesowicz viscosities are illustrated in Figure 7. The remaining two viscosities (γ_1 and η_{12}) have no direct analogue in isotropic liquids. Measurement of the viscosity of a nematic liquid crystal (η_{45}°) in a configuration intermediate between those shown in Figures 7 A and 7 B (i.e., with the director at 45° to the shear direction) leads to a contribution from a further term:

$$\eta_{45^\circ} = 1/2\,(\eta_1 + \eta_2) + 1/4\eta_{12}$$

The remaining rotational viscosity γ_1 opposes a pure rotation of the director, which can take place without any flow.

Figure 7. Shear and director geometry for measurement of the Miesowiscz viscosities η_1 (A), η_2 (B), and η_3 (C)

All these quantities can be measured by using a strong magnetic field to maintain uniform alignment, but the experiments are difficult and very few reliable sets of data are available for nematic liquid crystals.

In normal viscometry equipment (e.g., a capillary viscometer), the shear often results in an alignment of the director of nematic liquid crystal materials at a small angle to the direction of flow [22]. The flow viscosity measured under these circumstances approximates the Miesowicz viscosity η_2. As in measurement of η_2, therefore, the viscosity measured in the nematic liquid crystal phase is significantly lower than that of the isotropic liquid, and a discontinuity appears in the viscosity – temperature plot at the clearing point. The temperature dependence of viscosity otherwise approximates an Arrhenius behavior similar to an isotropic liquid [39].

3.4.7. Surface Alignment

The interaction of nematic liquid crystals with solid surfaces provides an important means of defining the director, and its control is crucial in almost all of the practical applications of liquid crystals. If a nematic liquid crystal is placed in contact with a glass surface, for example, the director lies at an undefined angle which is generally tilted out of the plane of the surface. Pretreatment of the glass, however, can determine unambiguously the director alignment at the surface. Rigorous cleaning or treatment with a surfactant leads to *homeotropic alignment* in which the director is perpendicular to the surface. Effective surfactants include silicones, quaternary ammonium salts, and metal complexes, which all have a long alkyl chain bonded to a polar head group. The head group is assumed to bond to the solid surface leaving the pendant alkyl group free to associate with the liquid crystal.

A wide range of treatments are also available to induce alignment parallel to a surface, sometimes termed *homogeneous or planar alignment*. Many polymers [e.g., polyamides, polyimides, and poly(vinyl alcohol)] are effective and can be deposited from an appropriate solvent.

In the absence of treatment, the director lies in an arbitrary direction in the surface plane. Mechanical rubbing of the polymer, however, imposes a preferred orientation direction on the surface. The director then lies along the rubbing direction and is tilted out of the surface plane by a small angle of ca. 1 – 5°. Rubbing bare glass with a fine abrasive, or oblique evaporation of a range of inorganic materials (e.g., magnesium fluoride or silicon monoxide) from a source ca. 30° out of the surface plane, leads to a zero tilt angle. Evaporation from a source ca. 5° out of the surface plane, however, gives a high tilt angle of ca. 20 – 30°. Because of the importance of surface alignment in the construction of displays, the technology has been explored in considerable depth [40], [41].

3.5. Nematic Liquid Crystal Materials for Display Use

The electro-optic display industry continues to motivate much of the development of liquid crystal materials worldwide. A range of physical properties must be manipulated simultaneously to optimize a fluid for each application. This is achieved by both the synthesis of new compounds and their incorporation into mixtures in new combinations. Since the invention of the first stable, colorless materials for displays in the 1970s, an unwillingness to accept new materials with photolytic, hydrolytic, or oxidative sensitivity has existed.

Materials for display use invariably consist of mixtures of liquid crystal compounds [42]. The first requirement for any such material is a nematic liquid crystal phase range extending beyond the anticipated working range of the device. For watch and calculator displays, a phase range from − 10 to + 60 °C is usual, whereas for industrial, automotive, and military applications a range from − 40 to + 90 °C is typical. No single compound exists that can meet these targets; mixtures extend the lower end of the phase

range by eutectic depression. The clearing point of a mixture T_{cl} does not suffer eutectic depression, but follows an additive relationship to the clearing points of the components T_i and their concentrations C_i:

$$T_{\mathrm{cl}} = \sum_i C_i T_i$$

The choice of components included in a mixture for a given application is based on the properties of available compounds. Account must be taken of the nonlinear variation of liquid crystal properties as the composition of a mixture changes, and mixture formulation usually relies heavily on measurement of the performance of trial samples in test devices.

In addition to their use in displays, nematic liquid crystals have been proposed for use in field sensors, thermal mapping, and nondestructive testing. Particular interest exists in third-order nonlinear optic processes in nematic liquid crystals that offer very high nonlinearity but slow speed [43], [44]. Both thermal and orientational nonlinearities exist.

3.5.1. The Frederiks Transition

Consider a thin sample of a nematic liquid crystal of positive dielectric anisotropy, contained between two parallel glass plates. Each plate is treated to induce planar alignment of the liquid crystal director along the same axis with zero tilt angle, and further carries a transparent electrically conducting layer beneath the aligning layer. The nematic liquid crystal adopts a uniform alignment throughout the thickness of the sample and is constrained by elastic forces that propagate from the surfaces (Fig. 8 A). If a voltage is applied between the plates, no torque on the liquid crystal molecules results, but the electric field tends to stabilize a tilted configuration of the director in the center of the cell because the tilt increases the apparent dielectric constant of the medium. In practice, no effect on director behavior is observed when the applied voltage increases until a critical value is reached at which the stabilization of tilt due to the increase in dielectric constant matches the elastic energy required to distort the director field. At this point a small tilt angle in the center of the cell, defined initially by a thermal fluctuation, is stabilized indefinitely by the applied voltage [45].

Figure 8. A Frederiks splay cell showing the off (A) and on (B) states

The initial deformation induced in the director orientation is a splay effect, and the onset of distortion is mediated by the elastic constant k_{11} (see Section 3.4.4). When the applied voltage is increased, the tilt angle at the center of the cell increases and the layers of liquid crystal closer to the surfaces also begin to adopt a significantly tilted orientation (Fig. 8 B). The deformation becomes a combination of splay and bend, and both k_{11} and k_{33} become significant. If the dielectric anisotropy of the liquid crystal is large, the variation in tilt through the thickness of the cell results in a corresponding change in the effective dielectric constant through the cell and a consequent redistribution of the electric field so that it is no longer uniform throughout the thickness. Both of these effects have consequences for the detailed form of the switching behavior in any particular liquid crystal material. In the cell described above, the tilt angle of the nematic director in the absence of an applied voltage is zero, and a degeneracy therefore exists between two states of equal and opposite tilt when a voltage above the threshold is applied. The direction of tilt is normally determined by a random thermal fluctuation, and different areas of the cell may tilt with the opposite sense. In this case, the uniformly tilted areas are separated by a defect known as a wall (Fig. 9).

At high voltage, the tilt of the director at the center of the cell effectively becomes 90°. The director at the aligning layers, by contrast, remains tied to the surface and consequently has a tilt of zero. Between these two extremes, the director adopts an equilibrium configuration determined by the conflicting elastic and dielectric forces. Under very high applied voltages the liquid crystal director becomes aligned perpendic-

ular to the surface except in a very thin boundary layer on each plate.

Figure 9. Wall defect separating domains of opposite tilt in a Frederiks cell

These phenomena may also be induced by an applied magnetic field, with only minor differences arising. In particular, the critical magnetic field is dependent on the thickness of the liquid crystal cell, whereas the critical voltage is not.

This field-induced realignment of a nematic liquid crystal is one of three types of Frederiks transition, the understanding of which is fundamental to the application of liquid crystals in electro-optic devices. Because the initial deformation is a splay, it is frequently referred to as the *splay* (*S*) *mode* transition. The remaining two Frederiks modes, the *bend* (*B*) and *twist* (*T*) *transitions,* are analogous to the splay transition but use different geometries of applied field and initial director configuration. The various types of Frederiks effect and the expressions for their threshold fields are summarized in Figure 10. Typical critical voltages (V_c) for common nematic materials are ca. 1 – 10 V, whereas in cells of the usual 10 – 100μm thickness, a threshold magnetic field (H_c) of $10^3 - 10^4$ gauss is common.

3.5.2. Electrically Controlled Birefringence

Consider a nematic liquid crystal cell in the configuration of the bend mode Frederiks transition (Fig. 10). The cell is placed between crossed polarizers. Because of the alignment of the nematic liquid crystal, the cell shows no birefringence and no light is passed. If a voltage higher than the Frederiks threshold is applied, the liquid crystal is reoriented. As a result, light propagates through the cell as ordinary and extraordinary rays that are polarized perpendicular and parallel to the direction of director tilt, respectively. The induced birefringence of the cell allows the transmission of light of intensity I:

$$I = I_0 \sin^2 (2\pi d \Delta n/\lambda) \tag{5}$$

where I_0 is the intensity of the incident light of wavelength λ and d is the cell thickness. Under a high applied voltage, Δn equals Δn of the liquid crystals. At intermediate voltage, a series of maxima and minima in the transmitted light intensity is observed. For practical materials and cell thicknesses, a $d \cdot \Delta n$ product of many times λ can be obtained, and a large number of such interference peaks and troughs is observed. One application of this technique is in measurement of the elastic constants of nematic liquid crystals. The first change in transmitted light intensity occurs at V_c. The constant k_{33} is obtained by substitution into the equation in Figure 10, $\Delta \varepsilon$ being measured independently; k_{11} and k_{33} can also be obtained from the switching curve above the threshold voltage. If a magnetic field is employed, changes in the geometry of the experiment may be used to measure the three elastic constants directly.

When mounted between polarizers, the Frederiks cell has the properties of an electro-optic modulator. To lower the degeneracy of the switched state and ensure that the tilt of the director is aligned correctly with the polarizers, surface treatment is required which induces a slightly tilted homeotropic alignment. This may be achieved by depositing a surfactant onto a rubbed polymer surface (see Section 3.4.7). Transmission of light in the field-on state is determined by Equation (5), with Δn replaced by the induced birefringence of the nematic liquid crystal. Transmission depends strongly on the wavelength of light λ, thickness of the cell d, and birefringence and, hence, temperature of the liquid crystal. In practice, if the cell is operated between a birefringence $d \cdot \Delta n$ of zero and $\lambda/2$, the device provides high contrast without undue sensitivity to temperature or wavelength.

The electro-optic effect described above is the basis of a class of liquid crystal displays known by various acronyms including the DAP (distortion of aligned phase) and ECB (electrically controlled birefringence) effect. This type of display has not been widely exploited because of the difficulties encountered in obtaining the

required alignment in a reproducible and stable manner, and in constructing devices with the necessary close tolerance on the liquid crystal layer thickness. Improvements in liquid crystal cell construction have, however, alleviated this problem, and the ECB display may find widespread application in the future.

Figure 10. Geometries and threshold fields of Frederiks transitions
Double-headed arrows indicate the alignment of the liquid crystal molecules. V_c = critical voltage; k_{11}, k_{22}, k_{33} = elastic constants; ε = dielectric constant; H_c = critical magnetic field; d = cell thickness, χ = diamagnetic susceptibility.

3.5.3. The Twisted Nematic Display

Problems of sensitivity to temperature, wavelength, and cell thickness are common to all liquid crystal displays that rely on variable retardation of light to generate their optical effect. All these problems are avoided in the twisted nematic display, which is the dominant display in digital watches, calculators, and other applications involving devices of moderate complexity [46].

Principles. The twisted nematic display consists of two parallel glass plates ca. 6 – 10 µm apart, the gap being filled with nematic liquid crystal [47]. Each glass plate carries a transparent electrically conducting layer, usually of sputtered indium tin oxide, etched into a pattern defining the switchable areas of the display. A rubbed polymer layer is used to provide planar alignment of the liquid crystal director, with a small surface tilt angle. The directions of rubbing of the polymer layers on the two glass plates are mutually perpendicular, so the alignment directions on the plates are also at 90° to one another. The liquid crystal adopts a twisted conformation, its alignment making a 90° turn through the thickness of the cell (Fig. 11 A).

Figure 11. Twisted nematic display showing off (A) and on (B) states

The optical properties of the twisted nematic layer are unique [48]: when $d \cdot \Delta n$ is large (the Mauguin limit), plane-polarized light entering the twisted nematic cell with the electric vector either parallel or perpendicular to the rubbing direction is transmitted through the cell, but the plane of polarization is rotated through 90° (Fig. 11 A). This behavior can be closely approached by using practical materials and cell thicknesses. If the twisted nematic cell is placed between crossed polarizers, the whole assembly transmits light.

The optical behavior of the twisted nematic layer has been analyzed by Gooch and Tarry

[49]. In a practical twisted nematic device, emergent light is elliptically polarized, and perfect transmission is achieved only for certain values of the parameter U, where

$$U = 2d \cdot \Delta n / \lambda \tag{6}$$

The general expression for transmitted light intensity is

$$I = I_0 - \frac{I_0 \sin^2 \left[(\pi/2) \left(1+U^2\right)^{1/2} \right]}{1+U^2} \tag{7}$$

which implies ideal behavior for values of U equal to $\sqrt{3}$, $\sqrt{15}$, etc., or for values of $d \cdot \Delta n$ equal to 0.48 µm, 1.07 µm, etc., for light at the peak of the eye's sensitivity curve.

The denominator in Equation (7) accounts for the perfect behavior in the Mauguin limit and also means that successive variations in the transmitted intensity become rapidly less significant as U increases. For values of U greater than about unity or for values of $d \cdot \Delta n$ greater than 1 µm, the light-guiding properties of the cell are sufficiently independent of cell thickness and wavelength. Most twisted nematic cells are constructed with a $d \cdot \Delta n$ of ca. 1 µm or higher, but if defects lead to areas in the cell being thinner than specified, the display shows bands of coloration. Some displays intended for applications in which a wide viewing angle is important, are constructed with a $d \cdot \Delta n$ of ca. 0.48 µm and are referred to as "first minimum" displays. In this case, a good appearance depends on accurate control of the cell thickness.

When voltage is applied to a twisted nematic cell, reorientation of the liquid crystal director analogous to the Frederiks splay mode transition takes place (see Section 3.5.1). Under a high applied voltage, the liquid crystal director becomes perpendicular to the plane of the cell except in a very thin layer adjacent to the glass plates. Under these circumstances the twisted structure of the nematic layer ceases to exist, the cell no longer rotates the plane of polarization of light, and the activated area appears black between crossed polarizers (Fig. 11 B). The familiar black digits seen on liquid crystal displays are merely areas where crossed polarizing filters extinguish light falling on the display.

In practice, the properties of a twisted nematic display are modified by the finite voltage applied. A liquid crystal drive voltage approximately three times the Frederiks threshold is commonly applied; under these conditions the tilt angle at the center of the cell does not reach 90°, providing an angle-dependent contrast in the display. Switching is obtained at the lowest voltage in a single quadrant of the display determined by the alignment direction on each glass plate. Practical displays give good contrast over a wide cone in the preferred viewing quadrant.

The twisted nematic cell is a very successful device that embodies many of the advantages and disadvantages of liquid crystal displays. It is a passive device; i.e., it does not emit light but modulates the ambient light that falls on it. The display appears dull under poor lighting, but it does not suffer from "washout" even in direct sunlight. Like most of the devices discussed here, it is a field effect device which does not rely on the passage of a current for its operation. This and the low working voltage contribute to an extremely low power consumption which makes twisted nematic displays ideal for portable, battery-operated, and even solar-powered equipment.

Multiplex Addressing. Another difficulty that remains to be addressed is achieving a high information density on liquid crystal display. The twisted nematic display described above is constructed by making a separate electrical connection to each active area of the cell (pixel), thereby using a total of 24 connections to a simple 31/2-digit watch display. On the same basis, an 8-digit calculator display requires 65 connections and any form of graphics display would be impractical. The solution lies in multiplex addressing of the display, which reduces the number of connections needed at the expense of restricting the voltages that can be applied to both "on" and "off" segments of the cell.

The twisted nematic display, like other nematic liquid crystal displays, responds to the root mean square (RMS) voltage applied to it [50]. A multiplex scheme can be implemented for RMS-responding displays, by configuring both backplane and the front of the display so that the patterns on the two glass plates are topologically equivalent to the rows and columns of an $X-Y$ matrix (Fig. 12). The number of columns in the matrix is equal to the multiplex rate M, and for

a display with N pixels the necessary number of connections becomes $N/M + M$.

Figure 12. Electrode patterns allowing three-way multiplex drive of a liquid crystal display composed of seven-segment digits
Connections for applying the bias and data voltages are shown in the upper and lower rows, respectively.

Multiplexed displays are addressed by supplying information to the pixels on column at a time, and using the RMS response of the liquid crystal to retain the information while the other columns are driven in turn. The whole display is, therefore, driven in M such addressing time slots. A voltage pulse (bias voltage) is applied to each column of the matrix in turn, and information is written on the rows by applying a simultaneous data pulse either in phase ("off" pixels) or out of phase ("on" pixels) with the column voltage. These pulses also appear as error signals on pixels lying on columns to which no bias voltage is applied. Optimal discrimination between "on" and "off" pixels can be achieved for a particular ratio of data (V_{d}) to bias (V_{s}) voltage which is characterized by the select level S [50]:

$$S = V_{\mathrm{d}} / (V_{\mathrm{s}} + V_{\mathrm{d}}) = 1 + \sqrt{M} \tag{8}$$

The RMS voltages applied to both "off" and "on" pixels are determined by the following equations:

$$V_{\mathrm{OFF}} = \frac{V_{\mathrm{SUPPLY}}}{S} \left[\frac{M - 1 + (S-2)^2}{N} \right]^{1/2} \tag{9}$$

$$V_{\mathrm{ON}} / V_{\mathrm{OFF}} = \left[\frac{M - 1 + S^2}{M - 1 + (S-2)^2} \right]^{1/2} \tag{10}$$

When Equation (8) is satisfied, Equation (10) can be reduced to

$$V_{\mathrm{ON}} / V_{\mathrm{OFF}} = \left[\frac{M^{1/2} + 1}{M^{1/2} - 1} \right]^{1/2} \tag{11}$$

A RMS multiplexed drive scheme, therefore, applies a voltage to both "on" and "off" pixels in a ratio determined by the multiplex rate (M). The magnitude of the voltages is also determined by Equation (9): in practice an integral value of S is used, close to (but not greater than) the optimal value of Equation (8).

Multiplexed addressing is the norm for liquid crystal displays, except for applications in which a wide viewing angle and a wide operating temperature range are of paramount importance. Typical multiplex levels employed are 2-way for watches and clocks, 3-way for calculators, and 8-way for a single-line alphanumeric display. Graphics displays use multiplex levels up to 256 ways or even higher. The threshold voltage of any material used in a multiplexed liquid crystal display must be adjusted to be a little higher than V_{OFF} to avoid turning on the nonselected pixels ("crosstalk"). The threshold voltage of a material in a twisted nematic cell parallels the Frederiks threshold voltage, which may be varied by adjusting $\Delta\varepsilon$. Liquid crystal mixtures are formulated which contain liquid crystal components of both large positive and small $\Delta\varepsilon$ [51] and variation of their relative concentration allows the threshold voltage to be adjusted to any value above ca. 1 V. As the desired multiplex level increases, $V_{\mathrm{ON}}/V_{\mathrm{OFF}}$ decreases and approaches unity, and the display fails to generate adequate contrast in areas addressed by V_{ON}, given the above limitation on V_{OFF}. This can be rectified only by improving the steepness of the optical switching curve. Significant progress in this direction can be made by optimizing the dielectric and elastic properties of nematic liquid crystal mixtures used in twisted nematic displays [52], but the twisted nematic display remains poorly suited to multiplex drive at ratios above ca. 32 ways.

3.5.4. The Supertwisted Nematic Display

Invention of the supertwisted nematic display has alleviated the difficulties discussed in Section 3.5.3 [53], [54]. It relies on display cells similar in construction to the twisted nematic display, but by a combination of surface alignment and doping the liquid crystal with a chiral additive, the cell is made to contain a higher degree of twist between 180° and 270°. As the

twist angle increases, the switching curve becomes steeper, until at some point it is vertical. Further increase in the twist angle results in bistable behavior where, over a certain range of applied voltage, both a high tilt and a low tilt director configuration are stable [55]. A practical limit arises from the occurrence of a two-dimensional texture at high twist angles, which scatters light and prevents smooth switching of the display. The effect can be alleviated by using alignment methods to give high surface tilt. Special polymers (e.g., poly-1,4-phenylene and fluorinated polyimides) can provide tilt angles up to 10° or more, which is adequate for twist angles up to 270°.

With a high twist angle (180 – 270°), construction of displays that guide light in the manner of a twisted nematic cell is impractical, and a birefringence mode of operation is used. The resulting device, denoted the supertwisted nematic (STN) or supertwisted birefringence effect (SBE), provides much better contrast and viewing angle than a twisted nematic display at moderate to high multiplex rates. Disadvantages of the technology are a relatively slow response speed, the need to make cells with very accurately defined and uniform thickness, and undesirable coloration of the display. Most supertwist displays operate in a blue (on state) on yellow (off state) mode, both states having their own birefringent interference colors.

The color of the off state can be removed by an ingenious but expensive technique [56]; a second liquid crystal cell having the same magnitude but opposite sense of twist is laminated to the first. Electrical connections are made only to one cell. The second cell acts as a compensator plate, eliminating the optical retardation in the off state of the display. Less perfect compensation may be achieved with a birefringent plastic sheet. Other, less satisfactory routes to neutral, colored, supertwisted nematic displays include the use of very low $d \cdot \Delta n$ products [57] or dyes.

3.5.5. Active Backplane Liquid Crystal Displays

The limitations on display complexity encountered in using a nematic liquid crystal display can be circumvented by construction of the device on a substrate carrying an array of active switching elements (→ Display Technology, Chap. 4.2.1.). Of the wide range of devices available [3], field effect transistors have been most widely used. Liquid crystal color television sets represent the state of the art in this technology, and most use amorphous silicon field effect transistors to control a twisted nematic display less than 10 cm across the diagonal. Prototype displays with a 35-cm diagonal have, however, been demonstrated. Color is obtained by a fine pattern of red, green, and blue filters deposited on the pixels.

3.5.6. Guest – Host Displays

An important property of liquid crystal materials, which is exploited in nematic displays, is their ability to align rod-shaped solutes that do not themselves show mesophases. This guest – host effect is particularly useful when the solute is a dye molecule because many rodlike dyes have an anisotropic extinction coefficient. A solution of such a dichroic dye in a nematic liquid crystal shows strong absorption of light only when the liquid crystal director is aligned with the polarization axis of the light. The effect is quantified in terms of the order parameter of the dye:

$$S = \frac{A_{\parallel} - A_{\perp}}{A_{\parallel} + 2A_{\perp}}$$

where $A_{\parallel}$ and $A_{\perp}$ are the absorbances of a cell to the light polarized parallel or perpendicular to the director of a dyed nematic liquid crystal contained therein. Practical dyes with an order parameter of ca. 0.8 are available in a range of colors [58].

The *Heilmeier display* utilizes a Frederiks splay mode transition in a dichroic dyed nematic liquid crystal [59]. One polarizer is used, with its axis parallel to the alignment on the adjacent glass plate, giving a strong absorption of light by the dye (Fig. 13 A). Application of a voltage to the cell leads to tilting of the director, and the absorbance decreases as the dye transition moment approaches a direction perpendicular to the polarizer axis (Fig. 13 B). To obtain full contrast, the liquid crystal host and the dye must realign perpendicular to the plane of the cell throughout its thickness. This requires application to the

cell of higher voltage than the 3 – 5 V commonly used for twisted nematic cells. Because switching begins at the Frederiks threshold voltage, the slope of the optical switching curve is not steep and the Heilmeier display is not suitable for multiplex drive. The optical density of the display is proportional to its thickness so that more accurate spacing is required than for a twisted nematic display, although much less stringent than for supertwisted nematic displays. Advantages of the Heilmeier display include the elimination of one polarizer, a better angle of view than in the twisted nematic cell, and brighter appearance.

Figure 13. Heilmeier display cell in the off (A) and on (B) state

The second guest – host display is the *White – Taylor* or *phase change display* [60]. This display employs a dichroic dyed nematic liquid crystal which is doped with a chiral additive to induce a helical structure (i.e., a cholesteric phase) with a pitch length shorter than the thickness of the liquid crystal layer. The cell is treated to induce planar alignment, and the liquid crystal adopts a twisted structure with the helical axis perpendicular to the plane of the cell. The tightly twisted liquid crystal structure cannot guide the plane of polarization of light, which propagates through the helix as a combination of two elliptically polarized rays.

In the presence of a dye, both rays can be absorbed efficiently; a low birefringence and short pitch favor this. When a voltage is applied, the switching does not resemble a Frederiks transition, because the dominant elastic force is no longer imposed by surface forces but is associated with the pitch of the liquid crystal. The helix is progressively distorted and unwound, a process that is complete at the associated critical voltage V_c:

$$V_c = \frac{\pi^2 d}{P}\left[\frac{k_{22}}{\Delta\varepsilon\cdot\varepsilon_0}\right]^{1/2}$$

where P is the helical pitch length in micrometers. Application of a higher voltage results in realignment of surface layers of dyed liquid crystal, which may make a significant contribution to the full contrast. The White – Taylor display is used in applications where its almost hemispherical angle of view is required. The absence of a polarizer also results in a bright appearance. However, a high drive voltage is necessary, and a contrast as high as that of the twisted nematic cell is very difficult to achieve. Typical uses are in backlit displays for instrument and aerospace applications.

3.5.7. The Dynamic Scattering Display

The display modes described in Sections 3.5.1, 3.5.2, 3.5.3, 3.5.4, 3.5.5, and 3.5.6 are all based on field effects; optical properties are changed by application of a voltage, without the need for current to flow in the device. By contrast, the dynamic scattering device, which initiated the widespread development of liquid crystal materials and technology, relies on current flow through the cell. When a current passes through a nematic liquid crystal of negative dielectric anisotropy, the passage of ions causes a variety of realignment effects. This results in a range of two-dimensional periodic structures that are dependent on the magnitude and frequency of the applied voltage [5]. In nematic liquid crystal materials with a resistivity up to ca. $10^9\ \Omega\cdot$cm and at low frequency, and moderate applied voltage these structures give way to a chaotic, highly turbulent state that scatters light strongly [61]. In the Schiff 's base derivatives which provided the first practical room temperature nematic liquid crystals (e.g., **4** in Table 1), conductivity was mediated by impurities and degradation caused by traces of water and oxygen entering the device. The resulting displays were extremely unreliable and had a short working life. Later dynamic

scattering displays utilized highly purified liquid crystals in hermetically sealed cells; conductivity was provided by addition of an ionic dopant. These displays were capable of good performance and long lifetime when correctly fabricated. The appearance of the scattering state is very dependent on the lighting and viewing conditions, and the necessity to pass current through the cell meant that the power consumption of dynamic scattering displays could never be as low as that of a field effect device. After invention of the twisted nematic display and a variety of very stable nematic liquids of positive dielectric anisotropy, the dynamic scattering mode fell out of use.

3.5.8. Polymer Dispersion Liquid Crystal Devices

The displays described in Sections 3.5.1, 3.5.2, 3.5.3, 3.5.4, 3.5.5, 3.5.6, and 3.5.7 consist essentially of glass plates having a suitable gap between them filled with liquid crystal material. This limits the size and type of device that can be made. Plastic displays allow the production of very large devices and possibly electrically controlled windows. The technology has been called the *nematic curvilinear aligned phase* (NCAP) device [62]. In this display, small droplets of a nematic liquid crystal material are dispersed in a polymer matrix [e.g., poly(vinyl alcohol)] by precipitation or emulsification. Once formed, the droplets adopt an alignment determined by the nature of the polymer surface, shape of the droplets, and statistical factors. Uniform alignment geometry throughout the droplet is impossible for topological reasons. Light passing through the polymer film is scattered by the droplets, giving an opaque appearance. Application of a voltage to electrodes on opposite sides of the polymer sheet results in realignment of the droplets to bring the director parallel to the field. If the refractive index of the polymer matrix equals n_0 of the liquid crystal, no effective difference in refractive index exists, and therefore no scattering of light that passes from polymer to liquid crystal or vice versa. The film appears clear and transparent under these conditions. Disadvantages of the device are that a high voltage is required and it is not suited to multiplex drive.

3.6. Thermotropic Cholesteric Liquid Crystals

Addition of an optically active dopant to a nematic liquid crystal induces a helical structure in the director configuration (see Section 3.5.6). The nematic phase may be regarded as the special case in which the helical pitch is infinite. The chiral nematic (i.e., cholesteric) phase has distinctive physical properties, particularly when the pitch is short.

If a chiral nematic liquid crystal is placed between glass plates and subjected to shear, uniform alignment (Grandjean texture) is induced in which the helical axis is perpendicular to the plane of the cell. In this state, the liquid crystal has dramatic optical properties [2], [5], [6] which are highly wavelength dependent and center on the wavelength that matches the pitch P of the helix:

$$\lambda = \bar{n} P$$

where $\bar{n}$ is the average refractive index. Centered on this wavelength is a band of width $\Delta\lambda$,

$$\Delta\lambda = \Delta n \cdot \lambda / \bar{n}$$

in which incident light parallel to the helical axis undergoes Bragg-like scattering from the helical structure, resulting in selective reflection of a circularly polarized beam. Only one polarization is reflected under these circumstances: a cholesteric liquid crystal with a right-handed helix reflects only right-handed polarized incident light, and left-handed polarized light passes through without hindrance. Moreover, the light is reflected as a right-handed polarized ray, in contrast to ordinary surfaces which reverse the sense of circular polarization on reflection. If a cholesteric liquid crystal with a left-handed helix is used, the same phenomena occur with obvious changes of polarity. Efficient reflection of light can be obtained from layers with a thickness up to 10 µm.

If light is incident from a glancing angle, the behavior is different [63]; second and higher order reflections may be observed. The principal effect, however, is that selective reflection occurs at shorter wavelengths, as predicted by the Bragg condition

$$\lambda = \bar{n} P \cos\theta$$

where the angle of incidence θ is measured from the normal to the plane of the liquid crystal layer.

Light falling outside the reflection band passes through the liquid crystal layer but undergoes rotation of the plane of polarization, which becomes very large and changes sign [64]. Applications of cholesteric liquid crystals are, however, derived from the reflection effect. At suitable pitch lengths, visible light of a single color is reflected from the liquid crystal layer. On passing through the clearing point transition, this reflecting color disappears abruptly. On cooling, the cholesteric phase forms a "focal conic" texture (so named from the appearance of conic sector curves in the texture when viewed under a polarizing microscope) that scatters light without any pronounced wavelength peak, and coloration of the liquid crystal is very weak. Such a clearing point transition therefore forms the basis of an "irreversible" temperature indicator: the operating temperatures of mixtures can be adjusted by use of variable proportions of components with high and low clearing points. The focal conic texture reverts to the planar texture spontaneously over a period of hours or days, or can be rapidly realigned by shear and, therefore, is not a truly permanent record of thermal history.

Liquid crystal mixtures can be prepared which possess a cholesteric phase and, at a lower temperature, a smectic A phase. When such a smectic phase is approached by reducing the temperature of the chiral nematic phase, the helix unwinds. The enthalpy of the smectic–cholesteric transition is very small, and pretransitional effects on pitch can extend tens of degrees from the transition temperature. In a cholesteric liquid crystal with this arrangement of phases and a very short intrinsic pitch length, cooling extends the pitch so that visible light is reflected. Continued cooling results in successive reflection of each spectral color from violet to red, followed by IR light. This is the normal mode of operation of liquid crystal thermochromic devices used for temperature measurement and novelty applications. By varying the optical activity of the material the width of the color play band can be adjusted; the temperature at which thermochromism occurs can be varied by adding components with higher or lower S_A–cholesteric transition temperatures.

The most common procedure for the construction of practical thermochromic devices is to microencapsulate the liquid crystal in droplets with a diameter of ca. 10–20 µm, each having a protective coating of gelatin–gum arabic coacervate (→ Microencapsulation). This coating protects the liquid crystal from contamination by fats, plasticizers, etc., and minimizes its exposure to atmospheric oxygen which can affect stability. The capsules are mixed into a binder system that allows them to be printed onto paper or plastic sheets. Other methods include polymer dispersion and plastic lamination [64]. In devices, the brightness of reflection is inferior to that observed in thin, pressed films of liquid crystal due to imperfect alignment, but the dependence of color on viewing angle is somewhat less.

Liquid crystal phases were first recognized in cholesterol esters; the first thermochromic devices used such materials. Cholesterol derivatives have continued to provide a source of optically active liquid crystal phases. A difficulty in formulating practical mixtures of cholesterol derivatives, however, is their generally high melting point combined with their relative instability. Purification of the low-melting compounds such as cholesteryl oleyl carbonate is also difficult. Because cholesterol is only available in the naturally occurring optically active form, variation of the pitch of mixtures relies on the addition of derivatives such as cholesteryl halides with an opposite twist. Mesogens with the largely saturated cholesterol skeleton have a low birefringence, which means that the selective reflection band is narrow and the perceived brightness is poor. All of these problems have led to the development of nonsteroidal liquid crystals. Derivatives of branched alkyl chains are available in both the optically active and the racemic forms. They often have short pitch lengths, and the sign and magnitude of pitch can be correlated with molecular structure [64–66]. Variation of the mesogenic core can be used to vary the birefringence and phase range of the materials. Series of mixtures based on such compounds have been developed with a wider range of temperature than is available from cholesterol esters [64]. Steroid derivatives and nonsteroidal

chiral nematics are now both exploited in devices; examples are listed in Table 4.

3.7. Blue Phases

In addition to the classic cholesteric phases described in Section 3.6, chiral nematic materials with a short pitch frequently pass through additional phases of short duration in the immediate vicinity of the clearing point [67]. Three separate blue phases have been identified, which are usually stable over an interval of no more than 1 – 2 °C. Blue phase I apparently consists of an array of twist disclination lines forming a body-centered cubic lattice. The phase arises from a local preference for a doubly twisted structure which cannot be sustained over long range in three dimensions for topological reasons. Blue phase II has a similar structure, but in this case a simple cubic lattice is formed. The structure of blue phase III, the "blue fog" phase, is unknown. Electro-optic effects have been demonstrated in the blue phases, but their narrow temperature ranges weigh heavily against their practical application.

3.8. Thermotropic Smectic Phases

Even in the least ordered smectic A (S_A) phase, the ordering of molecules into layers has fundamental consequences for the physical properties of the material. The only elastic distortion that is possible while maintaining a constant layer spacing is a bending of the layers (corresponding to a splay distortion of the director configuration); other distortions require the expenditure of energy akin to the compression of a liquid. This fact accounts for the divergence of k_{22} and k_{33} on approaching a smectic phase. Facile, reversible switching effects under an applied field, analogous to the Frederiks transition in nematic phases, are hardly observed in smectic materials. The smectic layers do not readily flow past one another. Flow in smectic phases is believed to occur by the movement of "plugs" of material through the bulk phase [5]. A very high apparent viscosity and strongly non-Newtonian behavior are observed in conventional viscometer geometries. The anisotropies of refractive indices, dielectric constants, and diamagnetic properties closely resemble those observed in nematic phases.

In view of its elastic behavior application of the S_A phase in electro-optic devices does not at first seem hopeful. Two different display technologies have nevertheless been demonstrated: thermally and electrically addressed devices.

Thermally Addressed Displays. Thermally addressed display devices utilize smectic material of positive dielectric anisotropy with a narrow nematic phase, enclosed in a display cell similar to that used for nematic liquid crystal displays [68–70]. In operation, an area of the cell is heated rapidly to a temperature above the clearing point of the liquid crystal. On cooling, the liquid crystal forms the natural microscopic structure of the smectic A phase which is the focal conic state. This texture contains a multiplicity of small domains in which director orientation varies rapidly; it therefore scatters light strongly. If an electric field is applied to the cell during heating and cooling, the liquid crystal aligns with the field during its passage through the nematic phase. Further cooling results in the formation of a uniform homeotropic smectic phase, and light scattering is not observed. Because of the high viscosity of the smectic phase, each texture remains indefinitely stable and information written on the display is stored without any refreshing. Application of the addressing voltage has no effect on areas of the display that are not heated. Separation of addressing into electrical and thermal processes circumvents the restrictions on display complexity imposed by RMS (root mean square) multiplexing. The information that can be written on the display is limited only by the resolution with which heat can be applied and the rate at which updating of the display is required.

Two variations of the thermally addressed smectic A display have been exploited. In the first, heating is performed by a laser focused onto the liquid crystal layer, the absorption of light usually being enhanced by inclusion of a suitable dye [71]. The second uses ohmic heating of rows of the display by means of stripe electrodes on one cell plate. On the other cell plate, column electrodes allow a voltage to be applied across the pixels which are to be driven into the clear state. Rows of the display are addressed in turn, and a small area device capable of video

rate addressing has been developed [70]. These devices have often been used in projection systems which take advantage of the high resolution to provide large, high-density data displays [68].

Electrically Addressed S_A Displays. An electrically addressed smectic A display has been demonstrated which also provides a high-density information storage device [72], [73]. The liquid crystal is doped to a resistivity of ca. $10^9\,\Omega\cdot$cm and is switched from a clear to a scattering state by dynamic scattering, which can be induced in S_A phases even if they have a high positive dielectric anisotropy. The process is reversed under dielectric forces, loosely analogous to a Frederiks transition. Discrimination between these two opposed switching processes is achieved by changing the addressing frequency, with scattering occurring at low frequencies. Such a device does not show an RMS response to applied voltage, and the characteristics of the display allow a very complex format to be achieved. The principal shortcoming is the high addressing voltages required (typically 50 – 80 V), which make this technology incompatible with the drive circuitry normally used for liquid crystal devices.

The S_C phase has the same degree of ordering as the S_A phase, but in the C phase the molecules in the layers are tilted and the phase is consequently biaxial. The macroscopic appearance of the S_C phase is very similar to that of a S_A phase, and the transition between these phases is frequently a very low-enthalpy process. The tilt angle in the C phase undergoes a pretransitional decrease as the transition temperature is approached. Systems in which S_C–N or S_C–I transitions occur, show a more abrupt collapse of tilt at the transition point. No significant applications presently exist for the common S_C phase, but the prediction and discovery of ferroelectric properties in the chiral C phase [74] and the demonstration of fast electro-optic devices exploiting the effect [75] have lead to extensive research.

Ferroelectric Displays. If an S_A phase is doped with a chiral additive or if its constituent molecules are optically active, a twisted structure does not result. In an S_C phase, a twisted structure results from helical ordering of the direction of molecular tilt in adjacent layers, and short-pitch S_C phases show selective reflection of light similar to that in cholesteric materials (see Section 3.6) [76]. The ferroelectric property of a chiral S_C phase, however, relies on the unwinding of this helix by surface forces or an applied field. Coupling between the chiral center of an S_C molecule and its environment then results in biaxial ordering, with a preferred orientation of transverse molecular dipole moments associated with COO−, C−Cl, C−CN groups etc. in a direction parallel to the layer and perpendicular to the tilt direction (Fig. 14). The resulting net dipole moment can be equated with the spontaneous polarization (P_s) of the ferroelectric phase. A chiral S_C phase can provide an electro-optic effect by aligning the material in the bookshelf geometry of Figure 15. The smectic layers and the spontaneous polarization vector are both perpendicular to the plane of the cell, and the molecules are constrained in the plane of the cell by surface forces. Two degenerate configurations then exist, with the molecular tilt to the left or the right of the layer normal; the P_s vector correspondingly points up or down from the plane of the cell. Switching from one configuration to the other can be accomplished by means of a short d.c. pulse, after which the states each have a limited bistability [75]. Each state remains stable over a much longer period than the switching time (i.e., for tens of milliseconds) in the absence of applied voltage pulses.

Figure 14. Microscopic ordering of chiral smectic C molecules
The combination of molecular tilt and steric influence (a) at the chiral center impose a biaxiality that orients the transverse dipole (b) in a unique direction without affecting the head – tail degeneracy of liquid crystal ordering.

Figure 15. "Up" and "down" domains of ferroelectric liquid crystal in the bookshelf geometry

When a surface-stabilized ferroelectric device is switched, it behaves as a uniaxial birefringent crystal in which the direction of the optic axis is rotated through twice the S_C tilt angle in the plane of the cell. This switching may be converted to an electro-optic effect by laminating crossed polarizers onto the cell, with one polarizing axis aligned parallel to the liquid crystal alignment direction in one switched state. This state appears dark, and contrast is obtained against the other switched state where light is transmitted due to optical interference arising in the same manner as in the "on" state of the electrically controlled birefringence effect (Section 3.5.2). The optical contrast of the ferroelectric cell is maximized when the optic axis rotates through 45°, and fortuitously this is achieved by a S_C tilt angle (22.5°) similar to that observed in many materials.

Interest in the switching of chiral S_C phases has been especially great because it can be achieved on a timescale of tens of microseconds, as compared to the tens of milliseconds required for the switching of common nematic displays. The device does not respond to RMS fields, but to a voltage – time product in the addressing pulses, and the threshold behavior and limited bistability of the cell allow multiplex drive at unlimited levels using specially designed pulse sequences. Complex displays have been demonstrated which use this effect [77–82]. Because the chiral S_C cell switches between two stable states, the intermediate liquid crystal configurations cannot be sustained; the cell switches from black to white without any intermediate grey shades being available. This obvious disadvantage for graphic and video displays may be overcome by spatial or temporal division of the addressing of each pixel [82], [83].

Several remaining difficulties distinguish this technology from other liquid crystal devices. The first is the necessity for construction of a very thin (< ca. 2 μm) device to stabilize the required bookshelf geometry of the liquid crystal. Because the device operates in a birefringent mode, a high degree of uniformity is required, and fabrication of large displays to such a tolerance presents considerable problems. Alignment of smectic phases is also difficult, and the properties of higher temperature phases are usually exploited to facilitate this [84], [85]. Mixtures can be formulated with the phase sequence $S_C - S_A - Ch - I$, in which the cholesteric phase is of very long pitch, but the spontaneous polarization of the S_C phase is large. Cooling such a mixture from the isotropic phase in a thin cell leads successively to a planar aligned nematic phase, a planar S_A phase, and an aligned S_C phase.

Bookshelf geometry is a very idealized view of the true state of alignment in S_C devices. Real cells contain defects [86], and a chevron structure appears to exist in the liquid crystal layer. Elucidation of the true structures in these devices [87] and development of addressing techniques [88], [89], cell fabrication methods, and improved materials [71], [90–95], are major themes in liquid crystal technology.

A range of materials suitable for chiral smectic C devices is listed in Table 5. The first liquid crystal materials in which ferroelectric switching was demonstrated were the unstable, high melting point compounds decyloxybenzylideneamino 2-methylbutyl cinnamate (**49**, DOBAMBC) and hexyloxybenzylideneaminochloropropyl cinnamate (**50**, HOBACPC), but room temperature materials have since been developed. To allow molecular engineering of the different physical properties required, mixtures are usually formulated from a nonchiral S_C base mixture containing one or more dissolved chiral additives (e.g., **52**, **53** in Table 5) to impart spontaneous polarization. The magnitude of P_s depends on the strength of the lateral dipole in the dopant and on the efficiency of its coupling to the chiral center: values of ca. 100 – 300 nC/cm^2 are attainable. Materials with a high P_s and long helical pitch are known, and pairs of dopants exist in which the sign of P_s is

Table 5. Compounds used in chiral S_C devices

Structure	Name	CAS registry number	Empirical formula	Use
$C_{10}H_{21}O$–C$_6$H$_4$–CH=N–C$_6$H$_4$–CH=CHCO$_2$CH$_2$CH(CH$_3$)C$_2$H$_5$ **49**	3-[4-(4-decyloxyphenylmethylene-amino)phenyl]-2-propenoic acid, 2-methylbutyl ester (decyloxybenzylidene-amino 2-methylbutyl cinnamate, DOBAMBC)	[*55593-53-8*]	$C_{31}H_{43}NO_3$	ferroelectric S_C compound

$C_8H_{17}O$–C$_6$H$_4$–C$_6$H$_4$–CO$_2$CH(CH$_3$)C$_6$H$_{13}$ **52**	4′-(octyloxy)biphenyl-4-carboxylic acid, 1-methylheptyl ester	[*62724-78-1*]	$C_{29}H_{42}O_3$	High P_s isotropic dopant
$C_8H_{17}O$–C$_6$H$_4$–C$_6$H$_4$–CO$_2$CH(CN)CH$_3$ **53**	4′-(octyloxy)biphenyl-4-carboxylic acid, 1-cyanoethyl ester		$C_{24}H_{29}NO_3$	high P_s isotropic dopant
$C_8H_{17}O$–C$_6$H$_4$–C$_6$H$_4$–CO$_2$–C$_6$H$_3$(F)–C$_5$H$_{11}$ **54**	4′-(octyloxy)biphenyl-4-carboxylic acid, 2-fluoro-4-pentylphenyl ester (MB805F)		$C_{32}H_{39}FO_3$	smectic C host
$C_{10}H_{21}O$–C$_6$H$_4$–CO$_2$–C$_6$H$_4$–OC$_6$H$_{13}$ **55**	4-(decyloxy)benzoic acid, 4-(hexyloxy)-phenyl ester	[*68162-09-4*]	$C_{29}H_{42}O_4$	smectic C host
$C_{10}H_{21}$–C$_4$H$_2$N$_2$–C$_6$H$_4$–OC$_8$H$_{17}$ **56**	5-decyl-2-(4-octyloxyphenyl)pyrimidine (PYP8010)	[*57202-62-7*]	$C_{28}H_{44}N_2O$	smectic C host

the same but the sense of helical twist is opposite.

A chiral, laterally dipolar S_A phase can show a form of induced ferroelectric behavior [96]. The ordinary S_A phase is uniaxial even when it is composed of chiral molecules, but application of an electric field to a planar aligned chiral S_A sample induces biaxial ordering of the lateral dipoles. This is coupled to the induction of a molecular tilt relative to the smectic layers, so that the optic axis of the phase rotates under the influence of the applied field. The tilt is proportional to the applied field; no threshold behavior or bistability occurs, so that the effect is not suitable for multiplex drive, but switching takes place on a comparable timescale (microseconds) to S_C switching. Induced tilt angles of $> 10°$ can be obtained close to an S_C–S_A transition temperature, but this value decreases at higher temperature. Potential applications of this device include fast shutters and modulators.

The remaining liquid crystal phases are relatively poorly explored with regard to their potential electro-optic applications. All chiral tilted smectic phases show switching behavior analogous to the chiral S_C phase. The bistability in these phases appears to be stronger and the switching considerably slower than in the S_C phase.

4. Thermotropic Discotic Liquid Crystals

The synthesis of thermotropic liquid crystals based on flat disclike (discotic) molecules was accomplished in 1977 [97]. Discotic nematic phases had previously been observed in mixtures obtained by pyrolysis of petroleum residues, but the structure was not clear. Discotic mesogens have been synthesized from a variety of core structures with four, six, or eight pendant chains (Table 6).

Discotic liquid crystals exhibit a polymorphism analogous to calamitic phases [9], [98]. Columnar phases contain stacks of discotic molecules; intermolecular distances within the stacks can be ordered or disordered, and the columns may be packed together in a hexagonal or a tetragonal array. The direction of molecular tilt within columns distinguishes different columnar tetragonal phases.

The discotic nematic phase is analogous to the corresponding calamitic phase, possessing only orientational ordering. The director is again defined along the unique (short) axis of a uniaxial phase. Because of the molecular form, a negative birefringence and dielectric anisotropy are more common in discotic phases and reentrant behavior also seems rather common. Discotic liquid crystals do not yet have practical applications, and all the mesophases are formed well above room temperature.

Figure 16. Illustrative structures of main-chain (A) and side-chain (B) liquid crystal polymers

5. Polymer Liquid Crystals

Polymers form both thermotropic and lyotropic liquid crystal phases, and the molecular architecture is subject to great variation [99]. Main-chain liquid crystal polymers incorporate mesogenic groups as part of the backbone, either alternating with flexible linking groups or forming a rigid rod polymer (see Fig. 16). In the latter, thermotropic liquid crystal phases are common only in copolymers whose structural irregularities serve to lower the melting point. Structural irregularities are introduced by copolymerization of bulky, flexible, or nonlinear molecules in a polymer composed largely of linear, rigid units. A typical example is the copolymerization of 2-hydroxynaphthalene-6-carboxylic acid with 4-hydroxybenzoic acid. Rigid rod homopolymers and regular copolymers may form lyotropic phases if a suitable solvent is available [100]. Many cellulose derivatives [101], [102], DNA fragments, and synthetic peptides [103], [104] also form lyotropic cholesteric phases in polar and semipolar solvents. The behavior of these lyotropic rod liquid crystals is qualitatively described by Flory's equation which, for rods with an axial ratio $x \gtrsim 10$, predicts liquid crystal

phase formation above a critical volume concentration V_c, where

$$V_c = \frac{8}{x}\left(\frac{1-2}{x}\right)$$

In systems where flexible groups are interspersed with rigid ones, the phase behavior and stability are qualitatively comparable with those of the isolated mesogenic moieties. The technological importance of main-chain polymers arises from the ease with which alignment of the polymer backbone can be achieved under shear forces. Alignment of these materials in a magnetic or electric field is very difficult, but the flow alignment that results from molding or spinning the polymer in the liquid crystal phase is preserved in the solid polymer and imparts exceptional anisotropic mechanical properties. These phenomena were first exploited in lyotropic liquid crystal polymer systems [105], [106] such as the polyamide **60**.

60

In solution in concentrated sulfuric acid, this polymer forms a nematic phase which on spinning yields fibers of very high tensile modulus and stiffness.

Thermotropic polymer liquid crystal systems have been extensively investigated [107] to avoid the inherent difficulties of lyotropic systems, which usually require aggressive solvents for their formation. Examples of thermotropic liquid crystal polymers follow:

61

62

63

They show additional advantages for molding [108] because flow alignment can result in improved mold filling and self reinforcement of the solid. Moldings exhibit good dimensional tolerance and small coefficients of thermal expansion.

The alternative fundamental architecture available for liquid crystal polymer systems is the side-chain or comb polymer (e.g., **64**, **65**), in which a conventional flexible polymer chain is replaced by mesogenic groups via a flexible link-ing unit [99]:

64

S_G 60 S_C 95 N 116 I

65

K 56 S_C 60 S_A 134 I

This concept has been extensively explored in polyacrylate and siloxane systems [109], and the resulting polymers show liquid crystalline phase behavior which frequently parallels that of the monomer. In polymers having pendant groups with strong terminal dipolar groups, however, smectic phase stability is enhanced, presumably due to cooperation among the polar association of mesogenic groups, the tendency of spacing groups to maintain the liquid crystal moities in parallel layers, and the effect of the liquid crystal groups on the flexibility of the polymer backbone.

Liquid crystal side-chain polymers show behavior similar to that exhibited by low molecular mass systems, but modified by the high viscosity typical of polymers. Polymers are now available which possess all of the liquid crystal phases exploited in low molecular mass systems in electrooptic devices. Alignment of the mesogenic groups can be achieved under electric or magnetic fields, but switching is normally very slow. Technological interest in side-chain polymer liquid crystals centers on systems that have benefits which are lacking in low molecular mass systems. In particular, smectic liquid crystal polymers offer the possibility of providing media for optical data storage with thermal and electrical addressing [110]. Use of a polymer provides a much more robust medium than low molecular mass materials. In an alternative approach a nematic polymer may be used, with data storage obtained when the polymer is cooled below the glass transition temperature, thereby freezing the order and alignment into place indefinitely. A similar technique can be applied to the production of specialized optical components [111]. Liquid crystal chiral smectic polymers may have potential as pyroelectric or piezoelectric elements, and polymer systems providing exotic materials such as liquid crystal elastomers may stimulate their own novel applications [112].

6. Amphiphilic Liquid Crystal Phases

A variety of amphiphilic surfactants associate with solvents to form liquid crystal phases in which the mesogenic units are aggregates of molecules [113]. At least four well-defined

Figure 17. Illustrative structures of amphiphilic hexagonal (A), lamellar (B), and cubic (C) phases
The structures shown here are not the only ones in each class of phase.

classes of mesophase exist in these systems (nematic, hexagonal, lamellar, and cubic, Fig. 17), with the possibility of different phases in each class.

At concentrations and temperatures above a critical point, surfactants in solution aggregate in a head-to-head, tail-to-tail fashion to form either infinite two-dimensional surfaces or curved closed structures (*micelles*). In a polar medium, the hydrophilic heads of the surfactant associate with the solvent, whereas the hydrophobic tails interact to form the interior of the micelles. In nonpolar solvents, the situation can be reversed, the micelles having their hydrophobic groups on the outside (reversed-phase structures). Micelles can be spherical, rod-like, or discotic in shape; the shape and structure of any particular surfactant are determined by the relative sizes of the hydrophilic and hydrophobic groups. The shape of the micelle is also affected by solvent, temperature, and concentration.

Lyotropic nematic phases are formed by polydisperse rod- or disk-shaped micelles, usually only within a very restricted area of a phase diagram. Mixed solvent systems frequently favor nematic phase formation. Like thermotropic nematic phases, these materials can be aligned in a magnetic field. The conductivity of most systems precludes dielectric effects. The birefringence of the phases is very low, and no practical applications have been devised.

Rodlike micelles of essentially infinite length pack into hexagonal structures. Normal and reversed phases of this type are known which form viscous anisotropic liquids. Micelles also form isotropic solutions in which a variety of effects such as flow-induced birefringence and viscoelastic behavior may be observed [114]. In contrast, the limiting case of large discotic micelles implies the formation of infinite layers or *lamellae*. These layers form liquid crystal phases in which lamellar bilayers are separated by aqueous layers. The phases are viscous and birefringent.

The fourth category of mesophase formed in amphiphilic systems relates to *cubic phases*, which may form in two ways. The first is by the close packing of spherical normal or reverse micelles. Such micelles show a positive curvature of the surfactant bilayer, but when a net negative surface curvature exists, a cubic structure can form in which both the aqueous phase and the surfactant form infinite continuous structures. Being cubic in nature these phases are not birefringent.

Although lyotropic phases have not been given the same prominence as thermotropic phases, their importance should not be underestimated. The phases are crucial in the manufacture and mode of operation of soaps and detergents, and have an important role in areas such as food preparation. Amphiphilic bilayers also form model systems for cell membranes [115], [116]. Finally, the possibility remains that lyotropic liquid crystals may be exploited in electro-optic devices in the future, and in this respect the formation of mesophases including nematic phases in dye systems appears interesting [117].

1. Introduction

Lithium [*7439-93-2*] (from the Greek word for stone, *lithos*), Li, atomic number 3, A_r 6.941, is the lightest element that is solid at normal temperature. Its natural isotopes ^{6}Li, A_r 6.015, natural abundance 7.42 %, and ^{7}Li, A_r 7.016, natural abundance 92.58 %, are not radioactive. The artificial isotopes ^{8}Li, ^{9}Li, and ^{11}Li have half-lifes of 842, 178, and 8.7 ms, respectively (→ Radionuclides). The electronic configuration of the free atom is $1s^2\ 2s^1$. The atomic radius is 0.155 nm (in the metal), and the ionic radius is 0.086 nm [1].

Lithium is a member of group 1 of the periodic table and thus has a valence of + 1. In many respects (e.g., the strong alkalinity of lithium hydroxide solutions and the reactivity of the metal) it has the character of an alkali metal, but it also exemplifies the diagonal relationship in the periodic table in its resemblance to magnesium: the metal forms only the oxide on combustion (not the peroxide), and with nitrogen it forms the nitride directly. Lithium carbonate, fluoride, and phosphate are very slightly water soluble. In contrast to sodium chloride, lithium chloride is soluble in polar organic solvents such as methanol.

History. The lithium minerals petalite and spodumene were discovered between 1790 and 1800 by Jose de Andrada in an iron ore deposit on the Swedish island of Utö. In 1817 August Arfvedson discovered the element lithium in this petalite deposit after finding discrepancies in his analytical values. Berzelius named the element lithion to indicate its occurrence in a stone. In 1818 Davy and Brandé first prepared lithium metal in extremely small amounts by electrolysis of lithium oxide with a voltaic pile. At about the same time, Gmelin discovered the red flame coloration produced by lithium salts. In 1825 Berzelius determined the lithium content of various mineral sources. The first preparation of the metal in gram quantities was achieved in 1854 by Bunsen and Matthiessen by electrolysis of molten lithium chloride.

For a long time, lithium and its compounds were of only minor interest (e.g., in pharmaceutical applications and as additives to glazes). Only after World War I did an appreciable demand for lithium develop, owing to its use in lithium-containing (0.04 %) lead-based alloys (Bahnmetall) for bearings. This was the reason for the first industrial production of lithium carbonate and lithium metal in 1923 based on the mineral zinnwaldite by the Hans-Heinrich works of the Metallgesellschaft in Langelsheim, Federal Republic of Germany. The availability of lithium carbonate in tonnage quantities made its industrial use possible, at first mainly in the ceramic industry. In 1929, the Maywood Chemical Works in the United States began production of lithium metal and lithium compounds based on German know-how. Lithium production in the United States increased substantially during World War II due to the use of lithium hydride as a convenient source of hydrogen, especially for small balloons carrying transmitter aerials for emergency use by ships and aircraft in distress and by lifeboats. This has been followed in the last 50 years by increasing use of lithium-based soaps in multipurpose lubricating greases for automotive and industrial use. A further upsurge in demand came from the nuclear industry: the isotope ^{6}Li yields tritium when subjected to a neutron flux (→ Nuclear Technology).

The world market for lithium and lithium compounds is now supplied mainly from production facilities in the United States and from the Salar de Atacama in Chile [Cyprus Foote Mineral, FMC Lithium Division, Sociedad Minera Salar de Atacama S.A. (MINSAL)], and from production by Chemetall GmbH (a subsidiary of Metallgesellschaft), Frankfurt/Main in Europe. In addition, China and the Soviet Union export some lithium carbonate and hydroxide and, to a lesser extent, lithium chloride and lithium metal. The small production facilities in Japan are for domestic use only. Between 1960 and 1964, lithium carbonate was produced by Quebec Lithium in Canada. Other minor producers of lithium carbonate and hydroxide, e.g., Maywood Chemical Works, Montecatini in Italy, Rhône-Poulenc in France, and Associated Lead Manufacturers in the United Kingdom, have all since ceased production for economic or technical reasons.

2. Properties

2.1. Physical Properties

Lithium, a silvery white metal, is the least dense of all known solids at room temperature, *mp* 180.54 °C, heat of fusion 431.4 J/g, *bp* 1342 °C. It has a very low Mohs hardness of 0.6 and is therefore very easy to form.

The density at 20 °C is 0.534 g/cm^3, and the density of the liquid between 200 and 1600 °C is given very accurately by the equation [2]

$$\varrho = 0.515 - 1.01 \times 10^{-4}\,(t - 200)$$

The vapor pressure at the melting point is calculated to be 1.88×10^{-8} Pa. Between 800 and 1400 °C, it is given by the relationship [2]

$$\log p = 10.4038 - 8283.1/T - 0.7081 \log T$$

The heat of vaporization is 22 705 J/g.

The dynamic viscosity at 180.5 °C is 0.599×10^{-3} Pa · s; between this temperature and 1000 °C, it follows the equation [2]

$$\log \eta = -1.5064 - 0.7368 \log T + 109.95/T$$

The surface tension σ at the melting point is 398 mN/m and, between 500 and 1600 °C, is given by [2]

$$\sigma = 0.16\,(3550 - T) - 95$$

The mean linear coefficient of thermal expansion α_{m} between 273 and 368 K is $56 \times 10^{-6}\,\mathrm{K}^{-1}$, and the mean coefficient of cubical expansion β_{m} between 291 and 453 K is $180 \times 10^{-6}\,\mathrm{K}^{-1}$. Lithium melts with a volume change of + 1.5 %. The volume of the molten metal between 185 and 235 °C is given by [3]

$$V_T = V_{298}\left[1 + 174.106 \times 10^{6}\,(T - 453)\right]$$

The specific heat c_p of lithium metal between 20 and 180 °C is $3.3 - 4.2\,\mathrm{J\,g^{-1}\,K^{-1}}$. For the molten metal at 450 °C, a value of $4.2\,\mathrm{J\,g^{-1}\,K^{-1}}$ is quoted. Between the melting point and 421.8 °C, the following equation is valid:

$$c_p = 1.083 - 2.00 \times 10^{-4} t$$

and from 421.8 to 895.3 °C:

$$c_p = 1.006 - 1.73 \times 10^{-5} t$$

The critical data are as follows: T_c = 3223 ± 600 K; p_c = 68.9 MPa; V_c = 66 ± 19 mL/mol; and ϱ_c = 0.120 ± 0.033 g/cm^3.

The thermal conductivity, in J s^{-1} m^{-1} K^{-1}, between 250 and 950 °C is given by

$$\lambda = 42.3 + 12.3 \times 10^{-3} t$$

The enthalpy, in J/g, between 500 and 1300 °C is given by [2]

$$\Delta H = -21.248 + 4.1902 \times t - 21.658/t$$

The ionization energy is 5.37 eV, and the electrode potential of the half cell ($Li \rightleftharpoons Li^+ + e^-$) is − 3.024 V.

Values in the range 0.23 – 0.31 nm have been quoted for the radius of the hydrated ion [4].

Metallic lithium has good electrical conductivity. The resistivity at 0 °C is 8.55 μΩ cm, and between 200 and 1000 °C it is given by

$$R = 18.33 + 3.339 \times 10^{-2} t - 6.795 \times 10^{-6} t^2$$

The electrical resistance increases with increasing density under pressure [3].

Between −180 °C and the melting point, lithium crystallizes in a body-centered cubic system (a = 0.35 nm at 20 °C). At ca. −190 °C, an allotropic transformation of α-lithium into a hexagonal modification with densest close packing occurs.

Very thin lithium films are reddish brown by transmitted light, a color similar to that observed with colloidal dispersions of lithium in inert liquids. Pure lithium vapor emits a red light. The arc spectrum of lithium between 607.82 and 230.22 nm exhibits more than 42 lines, the strongest of which is the red line at 670.8 nm; the orange line at 610.3 nm is also excited in a Bunsen flame. The red spectral line at 670.8 nm can be used to detect lithium chloride in amounts as low as 1.26 × 10^{-6} mg.

2.2. Chemical Properties

Lithium metal is very reactive, though considerably less so than other alkali metals. The presence of sodium as an impurity, even in amounts of 0.5 – 1 %, increases its reactivity, e.g., for the formation of lithium alkyls from lithium metal and organic halides.

A freshly cut surface of lithium metal has a silvery luster. At room temperature in dry air with a relative humidity of less than 1 %, the surface remains shiny for several days, although a very thin passive surface layer is formed that is hardly visible to the naked eye and consists mainly of lithium carbonate and oxygen-containing compounds [5]. Lithium metal can therefore be processed in dry air. However, in moist air a dull gray coating, consisting mainly of lithium nitride, lithium oxide, and lithium hydroxide, forms within a few seconds. If lithium ingots are allowed to remain in contact with air for some weeks, the reaction with atmospheric nitrogen extends into the interior of the metal with the formation of reddish brown lithium nitride and can lead to ignition. Even at room temperature dry nitrogen reacts slowly with lithium metal.

Protective gases for lithium metal include the noble gases, or pure sulfur hexafluoride up to 225 °C. Mineral oil is also suitable as a protective medium.

Lithium burns with a very luminous white flame, forming a dense white smoke consisting mainly of lithium oxide; the flame temperature is almost 1100 °C.

Burning lithium metal reacts with silicates (e.g., sand and concrete) and carbon dioxide. These substances are therefore unsuitable as fire-fighting agents, as is sodium hydrogen carbonate. Powdered limestone (calcium carbonate) and fire-extinguishing powders based on sodium chloride are suitable for fighting lithium fires. Another suitable material is Graphex (from the company CECA), a graphite – sulfate complex whose volume increases many times at high temperature, thereby effectively smothering the burning lithium.

Lithium reacts with water with formation of hydrogen, which ignites under normal conditions only if the metal is finely divided. Molten lithium reacts explosively with water.

Lithium reacts with hydrogen to form lithium hydride. This reaction is carried out on an industrial scale at 600 – 1000 °C. Lithium reacts with gaseous ammonia at elevated temperature to form lithium amide. The vigorous reaction

with halogens produces incandescence. Organic compounds containing active hydrogen or halogen usually react with lithium to form the corresponding organolithium derivative.

Lithium also reacts with boron, silicon, phosphorus, arsenic, antimony, and sulfur upon heating.

A suitable container material for molten lithium metal is low-carbon steel, up to ca. 700 °C. Because lithium reacts with carbides, carbon-steel vessels in contact with liquid lithium are destroyed by decarburization. Up to 1000 °C, niobium, tantalum, or molybdenum can be used; nickel is satisfactory up to 225 °C. Aluminum, calcium, magnesium, silver, platinum, and gold are attacked by molten lithium.

Lithium metal dissolves readily in liquid ammonia, the concentration of the saturated solution at −33.2 °C being 9.8 wt %. A saturated solution of lithium in ammonia has a density of 0.477 g/cm^3 at 19 °C, and is thus the lightest known liquid at this temperature. The concentrated solution has a bronze color, whereas dilute solutions show the blue color typical of alkali metals. Solutions of lithium in ammonia are used to produce lithium acetylide and for Birch reductions in organic chemistry.

3. Occurrence

Lithium is present in the upper 16 km of the earth's crust to the extent of ca. 0.006 %; it is the 27th most abundant element. Approximately 150 lithium minerals are known. Lithium enrichment in minerals took place in geological time by the fractional crystallization of molten magma. Lithium migrated to the low-viscosity molten phase which eventually solidified as pegmatite. Sometimes lithium ore deposits are also formed in the pneumatolytic phase, as shown by the frequent association of lithium minerals with pneumatolytically formed cassiterite. Typical examples of this are provided by the spodumene deposit at Manono in Zaire and at Kamativi in Zimbabwe. The lithium found in mineral water sources in magmatic zones was probably formed in a similar manner.

The four most important lithium minerals are amblygonite, spodumene, petalite, and lepidolite. Of these, spodumene and petalite are used directly in the form of ores or concentrates, especially in the glass industry, whereas spodumene concentrate is used in the production of lithium carbonate.

Natural brines with a high lithium chloride content, which are the end result of a natural leaching and evaporation process, are also important in the industrial production of lithium. Given the technology currently available, seawater, which has a lithium content of only ca. 0.17 ppm, cannot be regarded as a viable raw material for economic lithium production.

3.1. Important Lithium Minerals

Analytical data for the commercially important lithium minerals are given in Table 1.

3.1.1. Lithium Aluminum Silicates

Spodumene (triphane), $LiAlSi_2O_6$, has a theoretical Li_2O content of 8.03 %, but usually contains 6–7.5 % because of partial replacement of Li^+ by Na^+ and K^+. Spodumene has a monoclinic pyroxene structure consisting of $-SiO_3-$ chains linked together by aluminum ions, with the balance of the positive charge provided by lithium ions. Spodumene sometimes occurs in the form of large single crystals. Its color varies from white to gray-green to reddish. Very pure and transparent single crystals are regarded as semiprecious stones (kunzite). The high hardness value of spodumene (6.5–7 on the Mohs scale) leads to considerable abrasive effects when the material is worked. At ca. 1000 °C, naturally occurring α-spodumene undergoes an irreversible phase change to β-spodumene, whereby the volume increases greatly and the density decreases from 3.2 to ca. 2.4 g/cm^3. Spodumene ores consist of pure spodumene combined with quartz or feldspar; the Li_2O content ranges from less than 1 % to more than 5 %.

Petalite, $LiAlSi_4O_{10}$, has a theoretical Li_2O content of 4.9 % but usually contains only 3.5–4.5 %. It crystallizes in the form of monoclinic prisms and is white, gray, or reddish in color. It has a density of 2.4 g/cm^3 and a Mohs hardness of 6.5. Petalite decomposes at 1100 °C

Table 1. Typical analyses of lithium minerals, %

	Amblygonite	Spodumene concentrate	Spodumene, glassgrade	Petalite	Lepidolite
Li_2O	min. 7	min. 7	min. 4.8	min. 4	min. 3.5
K_2O	ca. 0.2	ca. 0.7	0.12	ca. 0.2	8 – 12
Na_2O	0.4 – 1.1	0.5 – 0.8	0.09	0.4 – 1.4	0.3 – 1.1
Al_2O_3	34 – 37	26 – 29	17 – 18	16 – 18	20 – 28
SiO_2	ca. 2.5	60 – 65	74 – 80	74 – 78	49 – 55
F	ca. 3.5	ca. 0.2	max. 0.1	ca. 0.1	4 – 6
Fe_2O_3	ca. 0.2	0.5 – 2	0.1 – 0.2	0.03 – 0.2	0.1 – 2
P_2O_5	44.5 – 50	ca. 0.5	max. 0.1	ca. 0.3	ca. 0.5
CaO	ca. 1	0.1 – 0.5	ca. 0.06	ca. 0.4	ca. 0.4
MgO	ca. 0.1	0.1 – 1	ca. 0.05	0.2 – 0.4	ca. 0.2

into β-spodumene and SiO_2. This transformation (and that of α-spodumene) is important in digestion of the ore.

Eucryptite, $LiAlSiO_4$, is a relatively rare lithium mineral that occurs mainly in combination with petalite, e.g., in Bikita, Zimbabwe. It has the highest Li_2O content (11.1 %) of the lithium aluminum silicates.

The three minerals are distinguished by their SiO_2 content:

Eucryptite: $Li_2O{\cdot}Al_2O_3{\cdot}2\,SiO_2$
Spodumene: $Li_2O{\cdot}Al_2O_3{\cdot}4\,SiO_2$
Petalite: $Li_2O{\cdot}Al_2O_3{\cdot}8\,SiO_2$

Thus, thermal transformation of petalite into β-spodumene and quartz can be regarded as a decomposition reaction.

3.1.2. Micas

The mica minerals form a subgroup of the aluminosilicates. They are sometimes formed by direct crystallization from molten magma but often owe their origin to pneumatolytic decomposition.

Lepidolite, $K[Li, Al]_3[Al, Si]_4O_{10}[F, OH]_2$, lithium mica, is the most important representative of this group. Depending on its origin and the weathering it has undergone, lepidolite can contain between 3.3 and 7.74 % Li_2O. Economic deposits contain 3 – 4 % Li_2O. The mineral is often pink to grayish violet and frequently contains 3 – 5 % rubidium and cesium oxides.

Zinnwaldite, which has the general formula $K[Li, Al, Fe]_3[Al, Si]_4O_{10}\,[F, OH]_2$, can be regarded as a variety of lepidolite with a high iron content. The Li_2O content varies with the actual composition of the mineral. The deposit in Zinnwald (Erzgebirge) contains 2 – 3 % Li_2O. Zinnwaldite is silvery to grayish brown, sometimes also tinged with red. The emerald green variety known as cryophyllite, found in Massachusetts, contains up to 5 % Li_2O.

3.1.3. Lithium Phosphates

Commercial amblygonite is a complex phosphate with the general formula $(Li, Na)Al(F, OH)PO_4$. Its principal constituents are pure amblygonite, $LiAlFPO_4$, with a theoretical Li_2O content of 10.1 %, and its hydroxyl substitution product, montebrasite, $LiAl(OH)PO_4$, with 10.3 % Li_2O. Amblygonite is milky white to gray in color, sometimes also with a brown or green tinge; it may have a sheen resembling a solidified stream of molten glass or a pearly luster. Deposits suitable for mining have an Li_2O content of 7 – 9 %, the highest of the commercially exploited lithium ores. However, amblygonite is never found in large accumulations but is widely distributed in small, usually lenticular deposits, often associated with other lithium minerals. Although amblygonite once was an important source of lithium, it is no longer regarded as a suitable source of raw material for today's large-scale lithium carbonate production plants.

Triphyline, $LiFePO_4$, and lithiophilite, $LiMnPO_4$, have a theoretical Li_2O content of 9.5 %. The known deposits yield a raw material

with 8 – 9 % Li_2O; however, they have not been commercially exploited because of their small size.

3.1.4. Other Lithium Ores

Lithiophorite, $[Li, Al]MnO_2(OH)_2$, is often found in veins of manganese ore.

Hectorite, which has the approximate composition $LiNaMg_8(Si_4O_{10})_3[F, OH]_6$ and contains ca. 1.2 % LiO_2, is the only lithium mineral that occurs in sedimentary rock and clay; it is classified in the montmorillonite group.

The unusual mineral zhabuyelite [6] was discovered recently in salt deposits in the Zha Buye lake in Tibet. It consists of colorless, transparent, monoclinic crystals of almost pure lithium carbonate.

3.2. Reserves of Lithium Minerals [7], [8]

The only mineral used as a raw material for the production of lithium compounds at present is spodumene, the largest known deposits of which are at Manono in Zaire. Reserves have been estimated to be over 2×10^6 t of lithium [9], [10]. New investigations by Lithium Australia into their own pegmatite deposits in Greenbushes (Western Australia) [11] have revealed reserves with 7×10^5 t of lithium, of which ca. 10 % is in the form of spodumene with more than 4 % Li_2O, ca. 50 % with more than 2.5 % Li_2O, and ca. 40 % with ca. 1.5 % Li_2O.

The U.S. producers Cyprus Foote Mineral and FMC Lithium Division base their operations on deposits in the "tin – spodumene belt" of North Carolina, which may contain as much as 2.8×10^6 t of lithium [9], [10]. Cyprus Foote Mineral ceased its spodumene operations in 1986. Since then it produces lithium only from brines.

The Canadian deposits at La Corne, which provided raw material for Quebec Lithium, are estimated to contain 10^5 t of recoverable lithium, with potential reserves of about twice this amount. Deposits belonging to Tantalum Mining Co. at Bernic Lake amount to ca. 60×10^3 t. The total known reserves in Canada are quoted as 6×10^5 t of lithium [12].

The deposits at Bikita in Zimbabwe consist mainly of petalite and lepidolite with some spodumene and eukryptite. They contain between 7.5×10^4 and 10^5 t of lithium. Russia has deposits of spodumene and lepidolite at Krivoj Rog and in Chita in Transbaikal. Other lithium minerals occur in the Altai mountains and on the Kola peninsula. No details are available concerning the extent of these reserves.

In northwest China, considerable reserves of spodumene containing ca. 1.5 % Li_2O have been reported in the southern slopes of the Altai mountains in the Koktohay – Aletai region. This provides raw material for lithium carbonate and hydroxide production in Urumchi. No details are available.

In addition to the principal reserves described above, a number of smaller ones exist in the United States, Canada, Australia, Zimbabwe, and China. Lithium minerals have also been found in Afghanistan, Argentina, Brazil, India, Madagascar, Mali, Mozambique, Namibia, and South Africa [13], [14].

The reserves in Europa are all of minor importance and so far have not proved worth mining. This is also true for the spodumene deposit that has recently been investigated in the Koralpe of Austria [15]. This contains 5×10^6 t of ore with an average of 1.7 % Li_2O. Spodumene has also been found in Lalin and near Caceres in Spain, Dublin in Ireland, and Tammela in Finland. Lepidolite deposits exist in France (Massif Central), Portugal, the island of Elba, Sweden, and central Finland. Petalite also occurs on Elba and at Utö in Sweden.

The confirmed lithium reserves based on pegmatite in the Western world are estimated at 3×10^6 t of lithium if recent figures from Greenbushes are included [16]; potential reserves amount to an additional 4×10^6 t [9].

Lithium ores are used directly or as flotation concentrate (sometimes mixed with other materials), e.g., in the glass industry or as slag formers in the foundry industry (see Chap. 9).

3.3. Lithium in Natural Brines

In the last decade, lithium-containing brines have become the most important raw materials for the production of lithium chemicals. Their industrial exploitation began at Searle's Lake,

California, in 1938 by Kerr-McGee Chemical, and in Clayton Valley, Nevada in 1966 by Foote Mineral (now Cyprus Foote Mineral).

In 1984, production of lithium carbonate from the brines of the Salar de Atacama in Chile was started by the Sociedad Chilena De Litio Ltda (SCL), now a 100 % affiliate of Cyprus Foote Mineral [17]. At the same Salar, Minsal S.A., a subsidiary of the Chilean mining company Sociedad Quimica y Minera de Chile S.A. (SQA, Soquimich) has also started its brine-based lithium carbonate production. In Argentina at the Salar del Hombre Muerto, FMC Corp. is building a new brine-based lithium extraction plant, due for start up in 1997.

Because of the extremely high solubility of lithium chloride in water, the basic concentration process for lithium-containing brines is natural evaporation such as occurs only in dry regions of the earth in particular geological formations [18]. The evaporation process leads first to increased lithium content in salt lakes, such as the Dead Sea or the Great Salt Lake. Further enrichment of lithium then takes place if the surface of the lake is completely dried out as in Searle's Lake and Clayton Valley. This enrichment also occurs in the last brines to be formed, which are enclosed in cavities. The surrounding salts can be practically lithium free or can contain up to 1500 ppm of lithium.

Important reserves of lithium-containing brines are found in western North and South America and in western China (Tibet and Qinghai Province) [6], [19], [20]. Their lithium contents vary greatly (see Table 2).

The reserves of lithium in these brines are sometimes considerable. It is estimated that the Salar de Atacama in Chile contains more than 1.1×10^6 t of lithium, Clayton Valley 7×10^5 t of lithium, and the Great Salt Lake 4.5×10^5 t of lithium. The quantities of lithium that can be recovered economically from these reserves are, however, much smaller. For the Clayton Valley they are estimated to be 4×10^4 t of lithium and for the Great Salt Lake, with coproduction of other salts, 2.6×10^5 t [9]. On the other hand, the amount of recoverable lithium from the Salar de Atacama, because of the higher concentration, is considerably larger (up to 8×10^5 t). A study by Amax Exploration of the recovery of 15×10^3 t/a of lithium carbonate as a coproduct with potassium chloride, potassium sulfate, and boric acid has been completed [21].

Not only is the lithium yield from brines reduced due to dilution caused by replacement of the withdrawn brine by fresh water, lithium is also lost through inclusion in salt crystals that form upon evaporation and in the sludge produced when magnesium is precipitated with lime. The verified reserves of lithium from salt lakes are estimated to be 1.8×10^6 t, and the potential reserves 18×10^6 t.

The recovery of lithium from material of low lithium content is also interesting, because of the importance of lithium to nuclear technology. An example is the proposed extraction from the Dead Sea by precipitation as lithium aluminate, $LiH(AlO_2)_2\cdot 5\,H_2O$ [22]. Also under investigation is the recovery of lithium from seawater [23] which, although it contains only 0.17 ppm of lithium (see Table 4), represents a total lithium reserve of 2.5×10^{11} t.

Another potential source of lithium is provided by subsurface brines associated with mineral oil. The brine lies beneath the oil layer and is often recovered at the same time as the oil. In Texas, the brines contain up to 692 mg of lithium per liter, but only rarely does the lithium content exceed 100 mg/L [24]. However, the high magnesium content presents a serious technical problem. For example, in the Smack-over brines in Arkansas the magnesium concentration is 20 times that of lithium. Given the other lithium resources available, industrial exploitation of the lithium in these brines does not appear to be feasable for economic reasons.

4. Production of Primary Lithium Compounds

4.1. Mining of Ore and Production of Concentrate

Lithium ores are recovered by quarrying or open-cut mining according to their location. Because the veins of ore are often only a few meters thick, the mining operation has to follow the veins, or open-pit mining must be used, which involves the removal of relatively large volumes of overburden. The ratio of overburden to ore is usually 3 : 1 – 5 : 1. An important exception is

the Greenbushes deposit in Australia, which has veins of ore up to 250 m thick.

If the lithium minerals are largely separated from the accompanying rock, preliminary sorting can be carried out by hand on a conveyor belt. In this way, it is possible to produce spodumene containing 4 – 5.5 % Li_2O from raw material containing 1 – 1.5 % Li_2O. A mechanical separation process, based on the difference in reflective properties between ore and gangue material, can also be used. This can give good results if the material is first suitably reduced in size.

The concentration of lithium ores by heavy-medium separation always entails large losses of lithium and has therefore not been used commercially.

A flotation process is employed on an industrial scale especially for spodumene [25]. The material is first ground to a grain size of less than 0.3 mm by using rod mills. Material finer than 0.075 mm is then removed (e.g., by hydrocyclone) because it would result in lower recoveries in the flotation process. Flotation agents such as anionic fatty acids in alkaline medium and sulfonated oils in acid medium are recommended. The use of cationic surfactants in hydrofluoric acid solution has also been proposed. The flotation process is carried out in a series of stages. Quartz, feldspar, and mica are concentrated in the foam, and spodumene is floated off. The spodumene concentrate contains 5.5 – 7.5 % Li_2O. It can be sieved into fractions with different lithium contents; the coarser fractions have the higher lithium contents. The yield of lithium from the raw mineral after concentration by flotation is 60 – 80 %, depending on the milling conditions used.

4.2. Ore Digestion and Production of Lithium Compounds

The digestion of lithium ore can be carried out with acid or alkali, or by an ion-exchange process using salts. Various processes are reviewed in [26]. Depending on the process and the digestion agent, the product obtained is lithium carbonate, lithium hydroxide, or lithium chloride.

Although amblygonite, triphyline, and lepidolite can be treated directly with the appropriate digestion agent, spodumene and petalite require pretreatment (decrepitation) to convert α-spodumene to β-spodumene, and petalite to β-spodumene and quartz. Decrepitation is carried out in rotary kilns at 1000 – 1100 °C. It results in a 30 % increase in the mineral's volume and a considerable improvement in its grindability.

4.2.1. Acid Digestion

The sulfuric acid digestion process can be used for all lithium ores. It is usually carried out at 250 – 400 °C, although 850 – 900 °C is recommended for amblygonite because this leads to the formation of insoluble aluminum phosphate which facilitates removal of the insoluble residue.

Sulfuric acid digestion gives a product that contains an insoluble residue, together with lithium sulfate which is leached from the crushed product with hot water. To remove alkaline-earth metals, aluminum, and iron, the solution is neutralized with lime and soda and then filtered. Lithium carbonate is precipitated by adding concentrated sodium carbonate solution. This is carried out near the boiling point, to take advantage of the decreasing solubility of lithium carbonate at higher temperature.

The sulfuric acid process gives good yields of lithium (ca. 90 %) and has a relatively favorable energy balance compared with other processes for the production of lithium compounds from ores. Digestion by hydrochloric acid or hydrogen chloride gas at 935 °C has been suggested for the production (by sublimation) of lithium chloride from lepidolite. This process has, however, little significance compared to the sulfuric acid process.

Figure 1. Flow sheet for lithium carbonate production from spodumene

The production of lithium carbonate from spodumene (petalite) by using sulfuric acid is described in detail in [25]. The flow sheet for the process is shown in Figure 1. The ore is first crushed to a particle size of 20 – 80 mm. Alternatively, flotation concentrate, which is already finely divided, is used. The crushed ore is fed into an oil-, coal-, or gas-fired rotary decrepitation kiln, which attains the required temperature (1050 – 1100 °C) over at least 10 m of its length. The spodumene takes ca. 4 h to pass through the rotary kiln, the dwell time in the decrepitation zone being 15 – 30 min, which results in practically complete transformation into β-spodumene.

The heat efficiency is improved by using a countercurrent flow of material and hot gas. The exhaust gases are used to preheat the ore, to heat the roasting furnace, and to concentrate the liquors by evaporation. The spodumene is quite hot as it leaves the rotary kiln, and sometimes a rotary cooler, which can also be used to preheat the combustion air, is necessary.

If the starting material is in lump form, the β-spodumene produced by decrepitation is crushed to a grain size of less than 0.1 mm. Sulfuric acid (93 %, in 35 % excess) is then added either by a mixer conveyor or by spraying onto a band conveyor fitted with a deflector plate. The digestion process, in which lithium in the ore is converted into soluble lithium sulfate, is carried out at ca. 250 °C in a lined rotary furnace or on a conveyor heated by exhaust gases, which carries the spodumene through a tunnel directly to the leaching stage. Digestion is usually complete in less than 1 h.

The lithium sulfate formed is leached out of the reaction product with hot water in Pachuca tanks agitated by compressed air or in stirred vessels. A continuous leaching process, in which the material and the water move countercurrently through several stirred vessels in series, has proved advantageous. After leaching, aluminum silicate residues are removed by a rotary vacuum filter, and the filtrate is treated with lime and soda to precipitate alkaline-earth metals and iron. After repeated filtration, the solution is neutralized with sulfuric acid. During neutralization and in the subsequent evaporation, which concentrates the solution to 200 – 250 g/L of lithium sulfate, aluminum hydroxide precipitates and is removed together with any purifying additives (e.g., activated charcoal).

The precipitation of lithium carbonate by concentrated sodium carbonate solution is carried out near the boiling point. Lithium carbonate is removed by filtration or centrifugation and washed with hot water to remove the adhering mother liquor (mainly sodium sulfate). It is then

dried with a vacuum plate dryer, a band dryer, or a vacuum screw conveyor dryer.

The particle size of lithium carbonate depends strongly on the concentration during precipitation, the temperature, and the rate of addition of sodium carbonate.

Mother liquor from lithium carbonate precipitation always contains ca. 1 g of lithium per liter and is therefore recycled. Before the liquor is returned to the leaching stage, sodium sulfate is removed by crystallization at low temperature. This is a valuable byproduct and improves the economic viability of the process.

The use of fluidized-bed furnaces has been proposed for the decrepitation process, enabling it to be carried out under mild conditions (see Fig. 2). Recycling of excess sulfuric acid from the dissolution process has also been proposed [27].

4.2.2. Alkali Digestion

Spodumene and lepidolite can also be digested by reaction with quicklime. Decrepitation of spodumene, calcination of limestone, and digestion are carried out in a single operation. Three parts of limestone are wet milled with one part of lepidolite, or 3.5 – 4 parts of limestone with one part of spodumene. The mixture is dried in a rotary furnace and then heated to the clinker point to give calcium orthosilicate and lithium aluminate together with excess lime.

The process is critically dependent on the temperature; lepidolite requires ca. 900 °C, and spodumene ca. 1040 °C. If the temperature is too high, a glassy clinker is formed, which severely hinders subsequent leaching of lithium hydroxide; too low a temperature leads to incomplete reaction. Control of the kiln is complicated because of caking and building up of the reaction mixture. In the case of lepidolite, the clinker obtained must be quenched immediately so that no reverse reaction occurs. Spodumene clinker may be cooled slowly, but quenching produces a clinker with better grindability.

After the clinker has been ground in ball mills, lithium hydroxide is leached out with water in several stages. The residues are then separated, and the solution is concentrated in multistage vacuum evaporators to crystallize lithium hydroxide monohydrate. The process has a relatively high energy requirement and gives a lithium yield appreciably below that of the sulfuric acid process. The lower yield is due to the problem of precisely controlling the kiln. For this reason, only the sulfuric acid process is used in the Western world. It is sometimes followed by the conversion of the lithium carbonate into lithium hydroxide. The production of lithium chloride by sublimation from spodumene mixed with calcium chloride and calcium oxide in a one-stage process with decrepitation at 1100 °C also has not become established.

4.2.3. Ion-Exchange Processes

Ion-exchange processes involve heating a lithium ore with a sodium or potassium salt. This leads to replacement of Li^+ ions in the ore by Na^+ or K^+ and formation of the soluble lithium salt of the anion used.

Figure 3. Schematic of an electrolytic cell for the production of lithium

The digestion of lepidolite by potassium sulfate at 825 – 875 °C has attracted much interest. Lithium is leached out as lithium sulfate and then separated from excess potassium sulfate. After evaporation, potassium sulfate is crystallized, and lithium carbonate is precipitated by addition of sodium carbonate to the solution. The potassium sulfate is then reused in the dissolution stage [28]. However, the loss of potassium in the form of potassium aluminum silicate in the insoluble residues is far from negligible, and for this reason the process is no longer used. If lithium production from lepidolite were to be resumed, the sulfuric acid process would probably be favored over ion exchange, because it also produces aluminum sulfate as a byproduct and is therefore more economical.

The digestion of β-spodumene with sodium or potassium acetate is carried out at ca. 400 °C [29]. It produces lithium acetate from which lithium carbonate is precipitated by addition of sodium carbonate; the resulting sodium acetate is recycled. In theory, the process consumes an amount of sodium carbonate equivalent to the lithium carbonate produced, the sodium acetate acting only as a carrier and remaining in the system. However, so far, the process has apparently been operated only on a pilot-plant scale.

The Quebec process of the Quebec Lithium Corporation is a modification of the acetate process in which β-spodumene is treated with aqueous sodium carbonate solution (30 % excess) at ca. 200 °C and 5 MPa for at least 10 min. A slurry of sodium aluminum silicate and lithium carbonate is formed, and subsequent treatment with carbon dioxide at low temperature dissolves the lithium, forming the soluble bicarbonate. The insoluble residue is a sodium zeolite that can be marketed. Lithium carbonate is precipitated from the solution by heating to the boiling point. The carbon dioxide generated is used again for the dissolution of lithium carbonate [30].

This process was used on an industrial scale until 1966. It requires considerably more energy than the sulfuric acid process because of the repeated heating of large quantities of water. Furthermore, sodium carbonate is lost through formation of sodium hydrogen carbonate during dissolution of the lithium carbonate with carbon dioxide.

In a further development of the Quebec process, pressure digestion of β-spodumene is carried out at 250 °C with aqueous sodium chloride solution made alkaline by the addition of 0.1 – 0.2 % calcium hydroxide. Lithium carbonate can be precipitated from the resulting liquor

by addition of sodium carbonate. Alternatively, lithium chloride can be isolated by solvent extraction (e.g., with *n*-butanol) [31].

4.3. Production of Lithium Carbonate from Brines

The lithium in brines is at present extracted commercially only at Clayton Valley and the Salar de Atacama. In Clayton Valley, the brines are pumped from wells up to 100 m deep into a series of solar ponds, in which the lithium concentration increases continuously while the accompanying salts precipitate due to oversaturation. The production process requires the lithium concentration to be at least 5000 ppm. If the initial concentration is 200 ppm, the enrichment factor must be at least 30 to obtain solutions suitable for the production process, because lithium losses take place by inclusion in precipitated salts and by seepage of the solution through the solar ponds. This means that at least 95 % of the water in the original brine must be evaporated. Such a process can only be operated economically where solar energy is sufficient to provide high rates of evaporation, i.e., in hot, dry regions of the earth. Brines containing 100 ppm of lithium can be concentrated economically if the magnesium content is low. The concentrated brine is purified and then sodium carbonate solution is added at high temperature to precipitate lithium carbonate, which is separated and dried.

Brines containing less than 100 ppm of lithium (e.g., from Searle's Lake) require a different process to recover the lithium, e.g., by precipitating it first as lithium sodium phosphate, Li_2NaPO_4. This lithium concentrate, known as licon, which contains 20 – 21 % Li_2O is then treated with concentrated sulfuric acid, converting it to phosphoric acid and a solid mixture of lithium and sodium sulfates. This is dissolved, and lithium carbonate is precipitated from the solution by addition of sodium carbonate. The yield of lithium in this process is ca. 88 %, which is very good in view of the low starting concentration. The economic viability of the process depends on the recovery of associated byproducts such as potassium chloride, sodium sulfate, sodium carbonate, borax, phosphoric acid, and bromine [32]. Lithium production at Searle's Lake was abandoned in the '70s.

5. Lithium Metal and Lithium Alloys

5.1. Production of Lithium Metal

Lithium metal is produced only by the electrolysis of molten lithium chloride, whose melting point of 614 °C is lowered by addition of potassium chloride. The lithium chloride – potassium chloride eutectic, with 44.3 % lithium chloride, melts at 352 °C. The salt mixtures used in industry contain 45 – 55 % lithium chloride, which allows electrolysis to be carried out at 400 – 460 °C.

The electrolytic cells most commonly employed (Fig. 3) resemble the Downs cell used for the production of sodium [33].

The cell and the cathode are constructed from steel, whereas the anode is made of graphite. Four cathode tubes are combined to form a unit, with each tube enclosing an anode cylinder. The anodes enter the electrolysis space from below, and the cathodes are supported by arms attached to the cell sides. The anode and cathode are separated by a wire-mesh steel diaphragm. The cell is equipped with an insulating inner lining, because both electrodes are introduced below the

surface of the melt. Lithium metal is formed at the cathode, rises to the top, and is collected under an argon atmosphere.

In the United States, lithium cells are sometimes operated without a diaphragm or ceramic insulating lining (Fig. 4) [34]. This greatly prolongs the lifetime of the cells but results in greater power consumption.

Another lithium electrolysis cell (Fig. 5) has neither ceramic insulation nor a diaphragm [35]. In this cell, a molten salt mixture containing the lithium metal formed rises continuously in the electrode space and is collected in an annular trough at the top of the cathode near the surface of the melt. It is then transferred through a siphon-like tube to a separation vessel connected to the cell, but isolated from the chlorine gas. Here, the lithium metal is separated from the electrolyte under an inert-gas atmosphere; the electrolyte is recycled, and the lithium metal is recovered.

The output of an individual cell is usually 200 – 300 kg of lithium metal per day. The decomposition voltage of lithium chloride is ca. 3.68 V, but in practice 6.0 – 6.8 V is usually required. The theoretical power consumption is 14.2 kW · h/kg of lithium, but the actual figure is 28 – 32 kW · h/kg of lithium. The current efficiency is ca. 90 %.

Lithium metal is shipped in steel drums or cans under an argon atmosphere or under a coating of oil. Lithium metal can be stored indefinitely in the absence of air.

Molten lithium can be cast in low-carbon steel molds without special precautions. Its low hardness enables it to be easily extruded or rolled. However, to maintain the silvery luster of lithium, the operation must be carried out in air of very low moisture content or under an inert-gas atmosphere.

5.2. Uses of Lithium Metal

The largest application of lithium metal is the production of organolithium compounds, principally butyllithium, and lithium hydride.

Lithium is used as a reducing agent in organic chemistry, as a solution in liquid ammonia for Birch reductions, and in the synthesis of vitamins [36].

A rapidly growing application of lithium metal is in sacrificial anodes in batteries. Lithium has a high electrochemical equivalent (3.86 A · h/g) and a low electrochemical potential (– 3.045 V). The main advantages of lithium batteries are high power output, extremely good storage properties (low rate of self-discharge), and relatively small power loss at low temperature (→ Batteries, Chap. 5.1.). Commercially produced primary cells have counterelectrodes made of manganese dioxide, chromium oxide (CrO_x), or graphite loaded with sulfur dioxide or thionyl chloride, and electrolytes consisting of lithium salts dissolved in organic solvents such as propylene carbonate or dimethoxyethane. They have cell voltages up to 3 V and energy densities up to 300 W · h/kg [37]. Secondary lithium cells, some based on aluminum – lithium alloys, are being investigated extensively [38], [39].

Lithium metal is becoming increasingly important as an alloying component (see Section 5.3); it is also used as a deoxidizing and desul-

furizing agent, especially for copper, nickel, and alloy steels.

Lithium and its compounds play a number of important roles in the nuclear industry, e.g., in the production of tritium, as a heat-exchange cooling medium, as a shielding material, and in the form of a molten salt mixture, as a solvent for other nuclear fuels.

These applications depend on the extremely large difference in neutron capture cross section and absorption distance between the two stable lithium isotopes (see Table 3) [40].

Table 3. Thermal neutron absorption cross section σ and absorption distance λ for lithium

Absorbent	σ, $cm^2 \times 10^{-24}$	λ, mm ∗
Natural isotopic mixture	71	3
^6Li	945	0.2
^7Li	0.0033	8000

∗ Distance at which radiation energy has decayed to 1/**e** of the original intensity.

Production of Tritium. The extremely large amount of energy released in thermonuclear reactions (see Table 4) is illustrated by the hydrogen bomb, in which tritium or its parent substance lithium in the form of $^6Li^2D$ reacts with deuterium nuclei.

Table 4. Thermonuclear reaction energies

Reaction	Energy, MeV
$^6Li(n, T)^4He$	4.8
$^7Li(n, nT)^4He$	2.5
$T(p, \gamma)^4He$	19.7
$T(D, n)^4He$	17.6
$T(T, 2n)^4He$	11.3

Several fusion reactions have been proposed for power generation (→ Nuclear Technology). Of these the reaction between deuterium and tritium

$$^2D + {}^3T \longrightarrow {}^4He + n + 17.6\,MeV$$

has the best prospect of success because it requires the lowest plasma temperature [41]. The tritium required for the reaction is produced from ^6Li by irradiation with thermal neutrons:

$$^6Li + n \longrightarrow {}^4He + {}^3T + 4.8\,MeV$$

The overall equation for the fusion reaction is [42]:

$$^6Li + {}^2D \longrightarrow 2\,{}^4He + 22.4\,MeV$$

This reaction takes place with loss of neutrons; therefore, neutron multiplication reactions (n, 2 n) are used to breed tritium, e.g., based on beryllium or using ^7Li as the starting material according to the equation

$$^7Li + n \longrightarrow {}^4He + {}^3T + n - 2.5\,MeV$$

Calculations based on this reaction show that 1 kg of natural lithium could produce 5×10^{13} J of energy.

Coolants. In addition to helium at ca. 5 MPa, the following coolants have been proposed for the cooling jacket of a fusion reactor: molten lithium metal, molten $LiF-BeF_2$, and molten lead containing 17 atom% lithium. In the latter materials the tritium breeding reaction can take place [41], [43]. An important parameter is the product of density and specific heat which shows that, compared with sodium as a coolant, a lower circulation rate of lithium metal (by a factor of 1.9) can be used. For $LiF-BeF_2$ this factor is 4.5 [44].

Solvents for Nuclear Fuels. Owing to the low neutron capture cross section of ^7Li, a mixture of ^7LiF (72 mol %), beryllium fluoride (16 mol %), thorium fluoride (12 mol %), and uranium tetrafluoride (< 1 mol %) has been proposed as a molten salt fuel for breeder reactors. In these reactors, which are envisaged as small power plants (e.g., in aircraft), the $LiF-BeF_2$ molten salt mixture acts as a solvent for the nuclear fuel [45].

Isotope Separation (→ Isotopes, Natural). The nuclear powers from time to time offer on the world market relatively large quantities of lithium hydroxide in which the natural ^6Li content is reduced by ca. 50 %. Separation of the lithium isotopes is carried out either by an isotope-exchange reaction between lithium amalgam and a lithium compound in solution [46] or by continuous ion-exchange chromatography of lithium salt solutions on special ion-exchange resins [47]. The isotopes ^6Li and ^7Li can be purchased with purities of 95 – 96 % and up to 99.9 %, respectively.

Lithium isotopes are supplied by the Isotopes Sales Department of the Oak Ridge National Laboratory and the US Energy Research and Development Administration.

5.3. Lithium Alloys

Lithium readily forms alloys with other metals such as lead, copper, silver, magnesium, boron, and aluminum [48]. Lithium often completely changes the properties of metals to which it is added, e.g., the hardness of aluminum and lead, or the ductility of magnesium.

The lead alloy Bahnmetall, which was developed in Germany in 1918 and contained 0.04 % lithium, is no longer important; it was used as a bearing metal for railroad cars until ca. 1955. A eutectic mixture of lead with 17 wt % lithium is used in nuclear fusion technology as a breeder and cooling medium.

The first aluminum – lithium alloy, containing 0.1 % lithium, was developed in 1924 in Germany under the name Skleron. In the United States in 1957, the alloy X-2020 (4.5 % Cu, 1.3 % Li, remainder Al) was used in the wings and horizontal tail surfaces of naval aircraft. During the 1980s, aluminum – lithium alloys have been developed continuously, especially by Alcoa, Alcan, and Pechiney. The low density of these materials, compared with the usual aluminum alloys, is of great interest to the aircraft industry. They will probably be used in the foreseeable future for military and large passenger aircraft, despite competition from carbon fiber-reinforced plastics.

Lithium is the only element, apart from beryllium, that simultaneously reduces the density of aluminum and increases its modulus of elasticity; furthermore, formation of the Al_3Li phase gives improved strength. Modern aluminum – lithium alloys are now based almost without exception on the system Al – Li – Cu – Mg – Zr [49]. The alloy 8090, for example, has the composition 2.5 % lithium, 1.3 % copper, 0.8 % magnesium, 0.12 % zirconium, and the remainder aluminum. Such alloys have a density about 10 % lower, and a modulus of elasticity ca. 10 % higher, than aluminum.

Aluminum – lithium alloys with the composition 50 mol % aluminum and 50 mol % lithium are used in primary thermal batteries in which the electrolyte (a mixture of salts) is melted before the battery is used.

6. Lithium Compounds [50]

6.1. Inorganic Lithium Compounds and Lithium Salts

Lithium amide [*7782-89-0*], $LiNH_2$, M_r 22.96, ϱ 1.18 g/cm^3, *mp* 373 °C, is a colorless compound that forms cubic crystals. It is converted to lithium imide, Li_2NH, above 400 °C, with loss of ammonia.

Production. Lithium amide is produced industrially by heating lithium metal or lithium hydride in a stream of ammonia. It also forms slowly when lithium metal dissolves in liquid ammonia.

Uses. Lithium amide is now used in many reactions in preference to sodium amide for safety reasons, and because it often shows greater selectivity. It is used as a catalyst for Claisen and aldol condensations; as an alkylation catalyst for amines, nitriles, ketones, and monosubstituted alkynes; and as a polymerization catalyst for acrylonitrile and methyl methacrylate.

Lithium acetate [*546-89-4*], $C_2H_3O_2Li$, M_r 65.99, is available commercially in the anhydrous form or as the dihydrate. Both are colorless powders that dissolve readily in water to give slightly alkaline solutions.

Production. Lithium acetate is produced by reacting lithium carbonate or lithium hydroxide with acetic acid.

Uses. Lithium acetate is used to a limited extent in pharmaceuticals. The technical grade is used as a component of catalysts for the production of polyesters [poly(ethylene terephthalate)] or as an additive to improve their physical properties. It is also added to organopolysiloxanes and acrylic polymers to prevent adhesion of ice.

Lithium benzoate [*553-54-8*], $C_7H_5LiO_2$, M_r 128.06, is used in the production of some synthetic polymers (e.g., to harden polyepoxides) [51].

Lithium citrate [*916-16-4*], $C_6H_5Li_3O_7$, M_r 209.92, is commercially available mainly as a di- or tetrahydrate and is used in the treatment of certain types of manic-depressive illness.

Lithium bromide [*7550-35-8*], LiBr, M_r 86.85, *mp* 547 °C, ϱ 3.463 g/cm^3, is a colorless, highly hygroscopic salt (→ Bromine Compounds, Chap. 2.1.2.). The saturated aqueous solution at 20 °C contains 59.8 % lithium bromide and, at 100 °C, 69.9 %. The vapor pressure of water above aqueous 52 % lithium bromide is 0.53 kPa at 25 °C, 4.98 kPa at 65.6 °C, and 48.1 kPa at 121 °C [52], [53].

Production. Lithium bromide is produced by treating an aqueous suspension of lithium carbonate with hydrobromic acid or by reacting lithium hydroxide with bromine. The latter reaction also produces lithium hypobromite, which is reduced to lithium bromide with formic acid or ammonia.

Uses. A 50 – 60 % aqueous solution of lithium bromide is used in air conditioners operating by the absorption principle. Solid lithium bromide is a component of oxidation and hydroformylation catalysts. It is also used for deprotonation and dehydration of organic compounds having acidic protons. Mixtures of lithium bromide and lithium carbonate in dimethylformamide are used to carry out mild dehydrohalogenation reactions [36], [54]. Lithium bromide is also used for the purification of steroids and prostaglandins, with which it reversibly forms complexes [55].

Lithium carbonate [*554-13-2*], Li_2CO_3, M_r 73.89, ϱ 2.11 g/cm^3, crystallizes as colorless monoclinic prisms that melt with slight decomposition at 732 °C. The technical product is a fine white powder with a bulk density of ca. 0.8 kg/L. Carbon dioxide dissociation pressures over lithium carbonate are as follows:

Temperature, °C	610	620	740	840	1000	1200
Pressure, kPa	0.1	0.3	1.9	3.8	9.2	30.4

Lithium carbonate is only slightly soluble in water; its solubility decreases with increasing temperature.

Temperature, °C	0	20	40	60	80	100
Solubility, g/100 g water	1.54	1.33	1.17	1.01	0.85	0.72

Lithium carbonate dissolves in aqueous carbon dioxide to form lithium hydrogen carbonate. Concentrations of 70 g/L of lithium carbonate at 20 °C and 0.1 MPa carbon dioxide pressure can be reached. Lithium hydrogen carbonate cannot be isolated. Aqueous solutions decompose on heating to form lithium carbonate and carbon dioxide. This reaction is used in the Quebec process (see Section 4.2.3) and for the purification of technical-grade lithium carbonate. Lithium carbonate reacts with acids stronger than carbonic acid to form the corresponding salts. Reaction with calcium hydroxide yields lithium hydroxide.

Production. Lithium carbonate is produced entirely from minerals or naturally occurring brines (see Chap. 4). The solution of lithium salts initially obtained (lithium sulfate, lithium chloride) is reacted with sodium carbonate solution and lithium carbonate is precipitated, or lithium hydrogen carbonate is formed first and then decomposed thermally.

Uses. Lithium carbonate is the starting material for the industrial production of all other lithium compounds and is itself used in industry in large quantities. It is an additive in glass, enamels, and ceramics [56], [57] (as are many lithium ores, e.g., spodumene and petalite). The lithium oxide generated by lithium carbonate is a very active flux for silica. It is increasingly replacing fluorspar (CaF_2) for environmental reasons. Its function is generally based on reduction of melting point (particularly important for enamels), reduction of viscosity of molten glass (leading to higher throughput and smaller wall thickness), increased surface tension (giving improved reflectivity to enamels and glazes), and improved chemical resistance. Lithium aluminum silicates with compositions in the range $LiAlSiO_4$–$LiAlSi_4O_{10}$ are produced that have extremely low or negative thermal expansion coefficients. These compounds and high-lithium glasses are used in heat-resistant ovenware.

The addition of lithium carbonate to cement or concrete leads to quicker setting. Amounts of 1 – 5 % are used to control setting times [58]. In quick-setting tile adhesives, lithium carbonate leads to faster adhesion of the tiles.

Lithium carbonate is also used as an additive to molten salt baths for the electrolytic production of aluminum. It reacts with aluminum trifluoride in the melt to form lithium fluoride. The concentration used is 2 – 5 %, preferably 3.5 %, of lithium fluoride. The following effects are produced: reduction of melting point (by

10 – 25 °C), density, and viscosity of the melt and an increase in electrical conductivity of ca. 10 %. This results in a reduced operating temperature, reduction in fluorine emission (up to 50 %), and savings in energy (2 – 3 %) and anode carbon (ca. 2 %). It is possible to operate existing electrolytic cells at higher loading (ca. 10 %), thus increasing capacity without additional capital investment [59–62].

Specially prepared high-purity lithium carbonate (conforming to the national pharmacopoeias, e.g., U.S.P., DAB, E.P., B.P., J.P.) is used increasingly for the treatment of manic-depressive conditions [63–65]; daily doses of ca. 150 – 500 mg of lithium carbonate are used. The successful treatment of herpes, alcoholism, and cancer by lithium carbonate assisted chemotherapy has also been reported [65].

Mixtures of lithium and potassium carbonate are used as electrolytes in molten carbonate fuel cells (MCFCs). The MCFCs operating at high temperatures (600 – 650 °C) are especially suited for modern coal-fired baseload electric utility plants and natural gas units. The high-quality waste heat can be used for industrial cogeneration or internal reforming [66].

Lithium chloride [*7447-41-8*], LiCl, M_r 42.40, *mp* 614 °C, *bp* 1382 °C, ϱ 2.07 g/cm^3, crystallizes in a cubic system. Its solubility in water is as follows:

Temperature, °C	20	40	60	80	100
Solubility, g/100 g water	83.2	89.8	98.4	111.9	128.3

Its solubility in ethanol at 25 °C is 2.5 g/100 g, and in methanol, 17 g/100 g.

Production. The known methods of producing lithium chloride from lithium ores have not been adopted commercially. At present, it is produced exclusively by reaction of lithium carbonate and hydrochloric acid, with special steel or nickel equipment because of the extreme corrosivity of lithium chloride. Concentration of the solution (e.g., in a vacuum evaporator) causes lithium chloride to crystallize. It is then separated from the mother liquor, dried, and packed in moisture-proof containers.

Uses. Lithium chloride is extremely hygroscopic; thus, like lithium bromide, it is used for drying gases and in air conditioners of the absorber type. Because molten lithium chloride readily dissolves metallic oxides, it is used as a component of fluxes and dipping baths for welding and brazing aluminum and light metal alloys. Most of the lithium chloride produced is used as starting material for the production of lithium metal by molten salt electrolysis.

Lithium cobalt(III) oxide [*12190-79-3*], $LiCoO_2$, M_r 97.87, ϱ 5.16 g/cm^3, can be used as a cathodic material in secondary lithium ion batteries [67]. The dark gray active material with a theoretical specific capacity of 137 mAh/g is prepared by sintering Li_2CO_3 with $CoCO_3$ at 900 °C. The first cells, of cylindrical design, have been commercialized by Sony [68].

Lithium hypochlorite [*13840-33-0*], LiOCl, M_r 58.39, is produced by reacting either chlorine with lithium hydroxide solution, or calcium hypochlorite (bleaching powder) with lithium sulfate. Unlike sodium hypochlorite, it may be obtained in solid form (e.g., by spray drying), although overheating must be avoided because oxygen is liberated above 100 °C.

Lithium hypochlorite is increasingly used as a disinfectant and bleaching agent for swimming pools and in food preparation areas (e.g., dairies and butcher shops). Its action in swimming pools is analogous to that of the cheaper calcium hypochlorite, but it does not increase the hardness of water and is completely soluble.

Lithium perchlorate [*7791-03-9*], $LiClO_4$, M_r 106.39, ϱ 2.428 g/cm^3, crystallizes from aqueous solution as the trihydrate (*mp* 95.1 °C), which is converted into the anhydrous compound at 130 – 150 °C via the dihydrate stage. Anhydrous lithium perchlorate melts at 236 °C and is stable up to 400 °C. Like lithium chloride, it is readily soluble in water (56.3 g/100 g water at 20 °C; 196.9 g/100 g water at 95.1 °C).

Lithium perchlorate is produced by reaction of lithium hydroxide or lithium carbonate with perchloric acid. It is used as a conducting salt in electrolytes for lithium batteries. Furthermore, solutions of $LiClO_4$ in polar aprotic solvents such as diethyl ether dramatically accelerate Diels – Alder reactions due to the Lewis acid character of the lithium ion [69].

Lithium tetrafluoroborate [*14283-07-9*], $LiBF_4$, M_r 93.74, ϱ 2.04 g/cm^3, and *lithium hexafluoroarsenate* [*29935-40-1*], $LiAsF_6$, M_r 195.85, are of potential interest as conducting salts for the electrolytes in lithium batteries.

Lithium hexafluorophosphate [*21324-35-3*], $LiPF_6$, M_r 151.90, 130 °C decomp., is highly soluble in aprotic solvents such as ethers and carbonates and decomposes slowly in water with formation of HF. Owing to its high solubility and electrochemical stability, it is the preferred conducting salt for secondary lithium batteries [70].

Lithium chromate [*14307-35-8*], Li_2CrO_4, M_r 129.89, is used as a corrosion inhibitor in air conditioners that contain lithium chloride or bromide solutions. It is made from lithium hydroxide and chromic acid.

Lithium fluoride [*7789-24-4*], LiF, M_r 25.94, ϱ 2.6 g/cm^3, *mp* 870 °C, is used as a flux for enamel and glass, and for brazing and welding light metals.

Lithium hydride [*7580-67-8*], LiH, M_r 7.95, ϱ 0.82 g/cm^3 (→ Hydrides, Chap. 2.2.), is used increasingly as a selective reducing agent for polar groups (e.g., esters, amides, nitriles) in organic compounds, although the complex hydrides are of much greater importance: e.g., lithium tetrahydridoaluminate [*16853-85-3*], lithium aluminum hydride, $LiAlH_4$ (see → Hydrides, Chap. 3.8., Chap. 3.9.), and lithium tetrahydridoborate [*16949-15-8*], lithium borohydride, $LiBH_4$ (see → Hydrides, Chap. 3.2., Chap. 3.3.). It can be used for the hydrogenolysis of Si – Cl bonds, for example, the production of monosilane (SiH_4) by the Sundermeyer process [71] and SiH-containing polymers [72].

Lithium hydroxide monohydrate [*1310-66-3*], $LiOH \cdot H_2O$, M_r 41.96, ϱ 1.83 g/cm^3, loses water on heating to form anhydrous *lithium hydroxide* [*1310-65-2*], LiOH, M_r 23.95, ϱ 1.46 g/cm^3, *mp* 462 °C.

Production. The production of lithium hydroxide monohydrate by digestion of spodumene with lime (see Section 4.2.2) has been replaced for economic reasons by the reaction between lithium carbonate and calcium hydroxide:

$$Li_2CO_3 + Ca(OH)_2 \rightarrow CaCO_3 + 2\,LiOH$$

This yields solutions containing up to 3.5 % lithium hydroxide. Attempts to work at higher concentration lead to loss of lithium carbonate in the calcium carbonate residue, because the solubility of lithium carbonate is reduced by the presence of lithium hydroxide. The reaction between these sparingly soluble starting materials requires intensive agitation and gives yields just over 95 % after many hours. The insoluble residue (mainly calcium carbonate) is removed, and lithium hydroxide monohydrate is crystallized from the mother liquor by evaporation, under vacuum if required. It is then separated and dried at 130 – 140 °C. Further heating to 150 – 180 °C produces calcined lithium hydroxide (LiOH). The removal of water can be accelerated by use of vacuum.

Other production processes that have been proposed include the reaction of lithium sulfate solution with barium hydroxide and the reaction of lithium carbonate with silicic acid in the molten state followed by hydrolysis of the lithium silicate formed. These processes are, however, of little more than academic interest.

The solubility of lithium hydroxide monohydrate in water is as follows:

Temperature, °C	20	40	60	80	100
Solubility, g/100 g water	21.6	22.0	23.1	25.6	29.6

Uses. Lithium hydroxide is used mainly for the production of lubricating greases. Over 50 % of the greases used today in motor vehicles, aircraft, and heavy machinery contain lithium stearates, mainly lithium 12-hydroxystearate. These greases have good viscosity properties up to 200 °C and are practically insoluble in water (→ Lubricants and Related Products).

Lithium hydroxide is also used in the production of dyes [73]. It has attained some importance as an additive to nickel – iron accumulators and, in its calcined form (98 % LiOH), as an absorbent for carbon dioxide in breathing apparatus, especially for crews of submarines and space vehicles. One gram of anhydrous lithium hydroxide absorbs 450 mL of carbon dioxide, so

that ca. 750 g of lithium hydroxide is sufficient to absorb the carbon dioxide generated by one person in one day.

Lithium hydroxide is also used in the building industry. As an additive to the mix water, it helps prevent the alkali – silica reaction, which is a cause of deterioration (cracking, disintegration) in portland cement concrete structures [74].

Lithium iodide [*10377-51-2*], LiI, M_r 133.29, ϱ 4.0 g/cm^3, is a yellowish crystalline powder that is prepared by reaction of lithium hydride with iodine in diethyl ether. It is used in organic syntheses to accelerate the aldol condensation of ketones with enolizable or nonenolizable aldehydes [75] and to cleave methyl esters and oxiranes [76]. Lithium iodide is also of interest for the manufacture of rapid solid ionic conductors [77]. *Lithium iodide trihydrate* [*7790-22-9*], $LiI \cdot 3\,H_2O$, M_r 187.34, ϱ 2.5 g/cm^3, is prepared by reaction of lithium hydroxide with hydriodic acid.

Lithium manganese oxide [*12057-17-9*], $LiMn_2O_4$, M_r 180.82, ϱ 4.28 g/cm^3 is a ternary spinel-type double oxide commonly prepared by sintering manganese oxide (MnO_2 or Mn_2O_3) with Li_2CO_3 at high temperatures. It is a potential cheap candidate for cathodes in high-power secondary lithium ion batteries. Practical specific capacities are in the range 90 – 120 mA h/g. [67], [78].

Lithium nitrate [*7790-69-4*], $LiNO_3$, M_r 68.95, ϱ 2.37 g/cm^3, is used, with other salts, to produce eutectic molten salt baths for vulcanization. A salt mixture consisting of lithium and potassium nitrates is available under the trade name Sabalith [79]. Unlike conventional nitrite-containing salt mixtures, Sabalith is not classified as a toxic substance, and it helps to reduce emissions of nitrous gases and carcinogenic nitrosamines.

Lithium nitride [*26134-62-3*], Li_3N, M_r 34.82, ϱ 1.38 g/cm^3, could attain industrial importance as a solid ionic conductor. It is also used together with magnesium boride and hexagonal boron nitride to prepare cubic boron nitride [80].

Lithium oxide [*12057-24-8*], Li_2O, M_r 29.89, ϱ 2.01 g/cm^3, is formed when lithium hydroxide is heated to 800 °C in vacuum. It is also obtained by the reaction of lithium metal with oxygen, which proceeds without formation of lithium peroxide.

Lithium peroxide [*12031-80-0*], Li_2O_2, M_r 45.88, ϱ 2.297 g/cm^3, is formed by reaction of lithium hydroxide solution with hydrogen peroxide; it can be isolated by careful evaporation in vacuum. It has some importance as a hardener for the formation of special polymers and for air purification in sealed spaces (submarines, breathing apparatus, space travel). One gram of Li_2O_2 produces 0.348 g of oxygen and absorbs 0.96 g of carbon dioxide.

Lithium double oxides are also known as lithium ceramics, and are used to a small extent in the ceramic and enamel industries. They include lithium aluminate [*12003-67-7*], $LiAlO_2$; lithium borate [*13453-69-5*], $LiBO_2$; lithium manganite [*12163-00-7*], Li_2MnO_3; lithium molybdate [*13568-40-6*], Li_2MoO_4; lithium silicate [*10102-24-6*], Li_2SiO_3; lithium titanate [*12031-82-2*], Li_2TiO_3; and lithium zirconate [*12031-83-3*], Li_2ZrO_3.

Lithium aluminate is of some importance as a construction material in fusion reactors [81] and fuel cells [82].

Lithium tetraborate [*12007-60-2*], $Li_2B_4O_7$, M_r 169.12, either pure or doped with beryllium or strontium as an internal standard, is used as a flux in X-ray spectroscopy and optical emission spectral analysis. It also has limited application in the manufacture of special lithium-containing, high-performance lubricating greases.

Lithium phosphate [*10377-52-3*], Li_3PO_4, M_r 115.79, ϱ 2.537 g/cm^3, is sparingly soluble in water (ca. 0.04 %). It is prepared by precipitation from solutions of lithium salts by addition of phosphates or phosphoric acid. It has some importance as a component of protective optical heat filters, in the corrosion protection of vessels for polyester production, and in the catalytic production of alkyl alcohol.

Lithium sulfate [*10377-48-7*], Li_2SO_4, M_r 109.94, ϱ 2.221 g/cm^3, *mp* 860 °C, is a colorless salt produced from lithium carbonate and sulfuric acid. It is used in the anhydrous or hydrated

form for the treatment of manic-depressive conditions [40]. It has also been considered for the production of quick-setting cements.

Other Lithium Salts. Lithium azide, borate, cyanide, molybdate, and salicylate, are prepared by reaction of lithium carbonate or lithium hydroxide with the corresponding acids. Lithium niobate and lithium tantalate single crystals are used as ferroelectric materials and also have acousto-optical properties that can be utilized in optical data transmission systems.

6.2. Organolithium Compounds, Lithium Alkylamides, and Lithium Alkoxides

The direct synthesis of organolithium compounds from metallic lithium and an alkyl or aryl halide was first described in 1930 [83]. The method is now used on an industrial scale. The compounds are usually prepared as solutions in hydrocarbons under a nitrogen atmosphere at 25 – 70 °C because they are thermally unstable. The presence of 0.5 – 2 % sodium accelerates the reaction. These precautions reduce the loss of yield by reactions of the type

$$RCl + RLi \rightarrow R_2 + LiCl$$

On completion of the reaction, excess lithium metal and the lithium chloride formed are removed by centrifugation, and the solution is clarified by filtration.

The lithium alkyls are oligomeric organometallic compounds with mainly covalent lithium – carbon bonds. They are oxidized by atmospheric oxygen to form the corresponding alkoxides. Compounds that contain active hydrogen, such as water, alcohols, phenols, acids, and primary and secondary amines, decompose lithium alkyls. For example, the reaction of water with butyllithium gives butane and lithium hydroxide, whereby the presence of oxygen may lead to spontaneous ignition. Commercially available 5 – 25 % solutions of butyllithium in hydrocarbons do not usually ignite spontaneously if they come in contact with air. However, if the contact involves a large surface area and higher concentration, spontaneous ignition is possible.

Because of their high reactivity, lithium alkyls are always stored and handled under nitrogen or noble gases. Carbon dioxide must not be used because it reacts exothermically with lithium alkyls. Suitable fire-extinguishing media are powdered limestone, powders containing sodium chloride, or sodium bicarbonate. Spillage of lithium alkyl solutions can be covered with powdered limestone and left to decompose in the air [84].

The most important lithium alkyls are *n*-butyllithium and *sec*-butyllithium.

***n*-Butyllithium** [*109-72-8*], *n*-C_4H_9Li, M_r 64.06, ϱ 0.765 g/cm^3, *mp* −76 °C, forms hexamers in the solid state and in hydrocarbon solutions. Neat butyllithium is a spontaneously flammable colorless and viscous liquid that can be distilled at 0.001 Pa and 80 – 90 °C. The commercially available neat *n*-butyllithium typically has a concentration of 90 % and a yellow color. *n*-Butyllithium is normally used as solution in hydrocarbon solvents. Those commercially available are:

Tech. *n*-hexane	15, 23, 90 %
Heptane	25 %
Cyclohexane	20, 24 %
Toluene	20 %

The hydrocarbon solutions normally do not ignite on contact with air, but as ignition cannot be ruled out and to avoid loss of active material, they must be handled under inert gas. The commercial solutions are thermally fairly stable: a 15 % (1.6 mol/L) solution in hexane decomposes at the rate of 0.06 and 0.25 % of the active material per month at 20 and 30 °C, respectively, forming 1-butene and lithium hydride [84]. In ethers, which are common solvents for reactions with organolithium compounds, butyllithium is much less stable. Donor solvents break down the butyllithium hexamers into more reactive tetra-, di-, and monomeric species. These species are more nucleophilic and tend to cleave polar bonds like the ether C – O bond. The half-life period $t_{\frac{1}{2}}$ of butyllithium at 25 °C in diethyl ether and 1,2-dimethoxyethane is 6 d and 10 min respectively. In THF $t_{\frac{1}{2}}$ is 23.5 h at 0 °C and 5 d at – 30 °C. Therefore low temperatures are normally required when ethers are used as cosolvents [85].

Production. Like all other commercially available organolithium compounds, *n*-butyllithium is manufactured from lithium metal and the corresponding organic halide. In principle, many aprotic solvents, including functionalized compounds like diethyl ether and unfunctionalized hydrocarbons, may be used. As alkyllithium compounds $C_nH_{2n+1}Li$ with $n \geq 4$ are miscible with hydrocarbons and these solutions are much more stable than those containing ethers or amines, commercial butyllithium synthesis is exclusively carried out in hydrocarbons at 30 to 60 °C.

$$C_4H_9Cl + 2\,Li \longrightarrow C_4H_9Li + LiCl$$

A satisfactory yield and a high rate of reaction are obtained only if the lithium metal is used as a fine dispersion containing about 0.5 – 2 % sodium. After completion of the reaction, the insoluble species (LiCl and excess lithium metal) are removed by filtration. An economic production requires the reprocessing of the insolubles to lithium metal (by electrolysis). The butyllithium is obtained as clear solutions containing small amounts of C_8 hydrocarbons.

Uses. Butyllithium is mainly used as initiator in the anionic polymerization of conjugated dienes [85–87]. In the first, stoichiometric step organolithium compounds carbolithiate the diene to give allyllithium-type species, which can undergo further insertion of excess monomeric diene to form so-called living polymers.

$$C_4H_9\text{–}Li + H_2C\text{=}CH\text{–}CR\text{=}CH_2 \longrightarrow C_4H_9\text{–}CH_2\text{-}CH\text{=}CR\text{-}CH_2\text{–}Li$$

The diene insertion can result in different stereoisomers: 1,4-addition gives either *cis*- or *trans*-polydienes, whereas 1,2-addition leads to *iso*- and *syndio*-polydienes containing vinyl groups. The resulting polymers exhibit a narrow molecular mass distribution, which can be adjusted by variation of the butyllithium concentration.

Polybutadiene rubber (BR) can be produced by Ti-, Co-, Ni-, or Nd-based Ziegler – Natta catalysts or by solution polymerisation with butyllithium (see also → Rubber, 3. Synthetic, Chap. 3.1.2.). In contrast to the high stereospecifity of the Ziegler catalysts (> 90 % *cis*-1,4 content) the lithium-BR microstructure is almost random (typically 30 – 50 % *cis*-1,4, 50 – 55 % *trans*-1,4 and 10 % 1,2-*iso* and *syndio*). Polar additives like ethers promote the formation of 1,2-addition products. Lithium-BR has an amorphous structure with very low glass temperatures, which is desired for typical rubber applications. Polyfunctional coupling agents such as $SiCl_4$ produce so-called star-polymers with excellent processability and abrasion resistance, used, for example, in the production of tires.

In contrast to butadiene, isoprene is polymerized by butyllithium with high stereoselectivity (90 – 92 % 1,4-*cis*) approaching that of the Ti-based Ziegler – Natta catalysts (98 % 1,4-*cis*). Synthetic polyisoprene rubbers (see also → Rubber, 3. Synthetic, Chap. 3.1.2.) are used in the same fields as natural rubber, which has exclusively a 1,4-*cis* microstructure.

Living polymers allow the preparation of block copolymers by sequential addition of different monomers. The most important products are styrene – butadiene rubbers (SBR), which are produced either in emulsion by radical-forming compounds or in solution, generally by using lithium-based initiators such as butyllithium. Depending on the reaction conditions, lithium-based SBR can either form random or block copolymers. The living polymers are coupled by terminating agents like 1,2-dibromoethane or $SiCl_4$ to give SBS three-block copolymers, which can be deformed at higher temperatures (thermoplastic elastomers). Thermoplastic elastomers containing 20 – 40 % styrene have a high tensile strength and are used for shoe soles, adhesion agents and as modifiers for bitumen and other thermoplastic elastomers like polystyrene. SBS-block copolymers with a higher content of styrene (about 70 %) are glass clear and have outstanding shock and impact strength. They are used for packaging foodstuffs or medical articles and for household articles like drinking beakers.

n-Butyllithium is also used in organic synthesis [88], [89] as a strong base for the deprotonation of hydrocarbons that are more acidic than butane, amines, and alcohols. An example is the manufacture of lithium diisopropylamide, which is an important reagent, mainly for the production of carbonyl or ester enolates:

$$C_4H_9Li + HN(C_3H_7)_2 \longrightarrow LiN(C_3H_7)_2 + C_4H_{10}$$

In aromatic chemistry metalation of the C – H bond is supported by heteroatomic sub-

stituents, and lithiation takes place in the *ortho* position (directed *ortho* metalation, DOM) [90]. As an example, 2,2-difluoro-1,3-benzodioxole is lithiated in the *ortho* position by *n*-butyllithium/TMEDA. The subsequent reaction with an electrophile yields an intermediate for the synthesis of the pyrrole fungicide Fludioxinil (Ciba Geigy) [91].

Butyllithium can be used for the preparation of other organolithium compounds by halogen/lithium exchange and for direct addition reactions to carbon – carbon, carbon – oxygen and carbon – nitrogen bonds. The most important reactions are summerized in Scheme 6 [89], [92], [93].

***sec*-Butyllithium** [*598-30-1*], *sec*-C_4H_9Li, M_r 64.06, is a spontaneously flammable, colorless, viscous liquid that forms tetramers in hydrocarbon solvents. It is commercially available only as 12 % solution in cyclohexane and methylcyclohexane. *sec*-Butyllithium is more nucleophilic and decomposes more readily than *n*-butyllithium. A 12 % solution in cyclohexane at 20 °C undergoes thermal decomposition to the extent of 1.4 % of the active material per month. The thermal decomposition yields butene gas and LiH; the latter is insoluble and responsible for the increasing turbidity of sec-butyllithium solutions on prolonged storage. Therefore solutions of *sec*-butyllithium must be kept cool during storage and transportation.

Uses. *sec*-Butyllithium is used as initiator for the solution polymerization of polydienes, especially styrene – butadiene block copolymers. In organic synthesis it is used when its higher reactivity compared with *n*-butyllithum is desirable.

***tert*-Butyllithium** [*594-19-4*], $(CH_3)_3CLi$, M_r 64.06, is a white crystalline substance which is pyrophoric in air and miscible with hydrocarbon solvents. The pure compound does not melt, but decompose above 140 °C. It can be sublimed at 100 Pa and 70 – 80 °C. In the solid state and in hydrocarbon solutions it forms tetramers. In hydrocarbon solution it is the most stable of the butyllithium isomers: at 20 °C a 15 % solution in pentane has a decomposition rate of only 0.015 % active material per month. Nevertheless it is the most reactive of the C_4H_9Li isomers, combining the highest basicity with reduced nucleophilic properties owing to steric effects. Ethers are more rapidly cleaved by *tert*-butyllithium than by its isomers.

tert-Butyllithium is produced in low-boiling hydrocarbons in a way similiar to *n*-butyllithium, but the yields obtained are considerably lower [92], [94].

The product is commercially available as 15 % solution in technical hexane and pentane.

tert-Butyllithium is very useful for introducing *tert*-butyl groups into organic and organometallic compounds. As example it can be applied for the synthesis of sterically hindered silane protecting groups:

$$t\mathrm{BuLi} + \mathrm{Me_2SiCl_2} \longrightarrow \mathrm{Me_2Si}t\mathrm{BuCl} + \mathrm{LiCl}$$

Because of the sterically demanding nature of the *tert*-butyl group, reactions with *tert*-butyllithium (e.g., deprotonations) can often be carried out with very high selectivity. *tert*-Butyllithium can also be used as convenient, homogeneous source of LiH. For example, trialkylborohydrides, which are inert towards commercial LiH, are converted to trialkylborohydrides with excellent yields [95]:

$$\mathrm{R_3B} + t\mathrm{BuLi} \longrightarrow \mathrm{Li[HBR_3]} + \mathrm{C_4H_8}$$

***n*-Hexyllithium** [*21369-64-2*], $C_6H_{13}Li$, M_r 92.11, ϱ 0.766 g/cm^3 is a pyrophoric colorless and viscous liquid in the neat state. It is commercially available as a 33 % solution in technical-grade hexane. Its reactivity resembles that of *n*-butyllithium and it can thus principally be used for the same applications. An advantage is that it does not form gaseous byproducts in deprotonation reactions and on hydrolysis, but liquid hexane instead.

Figure 6. Reactions of *n*-butyllithium (R = Bu; asterisk denotes products isolated after hydrolysis)

Methyllithium [*917-54-4*], CH_3Li, M_r 21.98, forms colorless cubic crystals. It is virtually insoluble in aliphatic and aromatic hydrocarbons. In ethereal solvents it is more stable than butyllithium; thus it is produced and is commercially available in ethers or ether-containing solvent mixtures. Commercial products are 5 – 6 % solutions in diethyl ether and ca. 8 % solutions in diethoxymethane [96]. These solutions are produced both with low or stoichiometric lithium halide (LiBr, LiI) content. THF-containing products are not stable on prolonged storage. Methyllithium forms tetrameric aggregates in THF and diethyl ether.

Uses. Methyllithium is used for the introduction of the methyl group into unsaturated substrates. In order to modify the selectivity, the methyl group is often transferred to a transition metal, e.g., copper [97]. These bimetallic carbanionic bases perform conjugate 1,4-additions to α,β-unsaturated carbonyls. As a typical example the production of an intermediate in the synthesis of the androgen Mesterolone is shown [98]:

Phenyllithium [*591-51-5*], C_6H_5Li, M_r 84.05, forms colorless monoclinic crystals. Commercial products are a 20 % solution in a mixture of about 70 % cyclohexane and 30 % diethyl ether and a 17 % solution in dibutyl ether. The solutions are brown in color and must be stored at low temperatures to avoid thermal decomposition. Phenyllithium is used as a mild metalating agent in organic synthesis and can be used instead of Grignard reagents to introduce phenyl groups into organic compounds.

Lithium *tert*-butoxide [*1907-33-1*], $LiOC(CH_3)_3$, M_r 80.06, ϱ 0.89 g/cm^3, *mp* 283 °C is a colorless compound with good solubility in many organic solvents (e.g. 16 % in hexane). It is commercially available as min. 98 % powder and as a 20 % solution in THF. In organic synthesis it serves as a strong base. As one of the few volatile lithium compounds, it sublimes without decomposition at 110 °C in vacuum, and is therefore a suitable raw material for lithium doping in CVD processes.

Lithium methoxide [*865-34-9*], $LiOCH_3$, M_r 37.98, is a white solid that is soluble in methanol but virtually insoluble in aprotic organic solvents. It is commercially available as a 99 % fine crystalline solid and as 10 % solution in methanol. It can be used as base, especially as catalyst for transesterification reactions.

Lithium diisopropylamide (LDA) [*4111-54-0*], $LiN(CH(CH_3)_2)_2$, M_r 107.14 is a white pyrophoric powder. Freshly prepared, it is soluble in hydrocarbons (in hexane about 10 %), but it tends to precipitate irreversibly from solution as a polymer on heating or prolonged storage. In ethers the solubility is much higher, but with the exception of tetrahydropyran [99], LDA is decomposed at a rate depending on the ether, concentration, and temperature.

LDA can be conveniently prepared from butyllithium and diisopropylamine or purchased as a 2 mol/L (25 %) solution in THF and a mixture of various hydrocarbons. Although LDA is unstable in pure THF (at room temperature a 25 % solution loses about 1 % of its activity per day), the commercially available compositions containing only a limited amount of THF are satisfactory stable for technical applications.

Uses. LDA is a sterically hindered nonnucleophilic strong base used for selective deprotonations, especially for the production of kinetic enolates (i.e., the thermodynamically less favored isomer) and (hetero-)aromatic carbanions. In the production of the serum lipid regulating agent Gemfibrozil one key intermediate is formed by quenching an ester enolate with 1-bromo-3-chloropropane [100]:

Lithium bis(trimethylsilyl)amide [*4039-32-1*], lithium hexamethyldisilazide (LHMDS), $LiN(Si(CH_3)_3)_2$, M_r 167.33, *mp* 106 °C, *bp* 115 °C/100 Pa, forms colorless crystals which are very soluble in many aprotic solvents like toluene, hexane, THF and *tert*-butyl methyl ether. This base is more stable, less basic, and less air sensitive than lithium diisopropylamide. It is commercially available as a 20 % solution in THF and as a 30 % solution in hexane and other solvents. Like LDA it is used as nonnucleophilic base to generate kinetic ketone and ester enolates. It is considerably more selective than LDA and undesired reductions (e.g., of nonenolizable ketones observed in the case of LDA) can be avoided by using LHMDS.

7. Quality Specifications and Analysis

Lithium metal [*7439-93-2*] of standard grade has a purity in excess of 99 % and contains ca. 0.5 % sodium. Battery grade lithium contains less than 200 ppm of sodium. Standard quality lithium is usually produced in the form of bricks or cylinders 0.1 – 1 kg in weight, rods with a diameter of 10 – 20 mm, or granules with a diameter of ca. 2.5 mm. Battery grade lithium is supplied as foil with a thickness down to 0.03 mm.

Lithium is detected qualitatively by its characteristic red flame coloration; this is also used for quantitative determination by flame emission spectroscopy, in which the emission line at 670.8 nm is measured. Analysis is carried out by using diffraction or refraction spectrometers. In the presence of interfering ions, especially other alkali metals, a calibration curve should be used to obtain adequate accuracy (± 1 %) [101].

Lithium can also be determined by gravimetric, titrimetric, and colorimetric methods,

after precipitation as the periodate, phosphate, zinc uranyl acetate, aluminate, or fluoride [102]. Lithium sulfate can be used as a primary standard. Lithium hydroxide and organolithium compounds can be determined easily by acidimetric methods. Indirect methods for the determination of lithium salts are also used, e.g., separation of the lithium by ion exchange followed by titration of the acid produced and, for lithium salts of organic acids, by titration with perchloric acid in nonaqueous media [103].

Analysis of lithium hydrides can be carried out by measuring the volume of gas evolved on hydrolysis. For low concentrations of lithium, ion-exchange chromatography is most suitable [104].

8. Toxicology and Occupational Health

The lithium ion is considerably more toxic than the sodium ion; for example, 5 g of lithium chloride can cause fatal poisoning. On the other hand, lithium salts have been widely used for over 30 years for the clinical treatment of manic-depressive illnesses. Therapeutic doses of 170 – 280 mg Li per day, mainly in the form of lithium carbonate, are administered over long periods. Lithium is an environmental trace element. Estimated background exposure is 2 mg/d and is believed to have beneficial effects [105].

In Europe and the United States, there are no special regulations concerning lithium in wastewaters. Lithium is included as a part of the allowed salt emissions.

No industrial disease caused by ingestion of lithium compounds has been reported thus far. Lithium hydroxide has caustic properties similar to those of other alkali-metal hydroxides; the caustic action of lithium hydride and lithium aluminum hydride is due to the lithium hydroxide formed on hydrolysis. Details of the toxicity and therapeutic possibilities of lithium are given in [63], [65]. The special safety precautions necessary when handling the often pyrophoric organolithium compounds have already been referred to (see Section 6.2).

9. Economic Aspects

The information available concerning world production of lithium ores is incomplete [106]. Including those amounts used for lithium carbonate production, it can be estimated at 6×10^5 t/a.

In 1992 the estimated consumption of lithium minerals in the Western world for direct use (e.g., in the glass, ceramics, and metallurgical industries) was 85.5×10^3 t/a, corresponding to about 12×10^3 t of lithium carbonate equivalents. A further $(150-200)\times10^3$ t was used in the production of lithium chemicals.

The bulk prices (FOT Amsterdam) in May 1995, in U.S. dollars per ton, were

Petalite (4.2 % Li_2O)	147
Spodumene concentrate (> 7.5 % Li_2O)	385
Glass-grade spodumene (5 % Li_2O)	175

The consumption of lithium compounds (calculated as lithium carbonate) in the Western world was ca. 3.2×10^4 t in 1989, with an annual rate of increase of ca. 3 – 4 %. Approximately 40 % of the lithium production was consumed by the United States, where, together with Chile, the main ore and brine deposits are to be found. The capacity available at present together with the projected expansion will ensure that the market remains satisfied. About 25 % of the lithium produced is used in the lubrication industry, 25 % in the aluminum industry, 25 % in the enamel, glass, and ceramic industries, and the rest for miscellaneous uses such as chemicals, pharmaceuticals, catalysts for the rubber industry, additives for welding materials, and absorbers in air conditioners.

Bulk prices in the United States in November 1996, in U.S. dollars per kg, were:

Lithium carbonate	4.25
Lithium hydroxide monohydrate	5.73
Metallic lithium	89.51
Lithium chloride	8.91
n-Butyllithium	47.18

1. Introduction

Local anesthetics are compounds that reversibly inhibit the excitability of sensory nerve endings or the conductivity of neuronal pathways to pain or other sensory stimuli in a restricted area without causing permanent damage. This blockade prevents the perception of pain (analgesic action) or painlike sensations (anesthetic action); other sensations such as pressure can, however, still be felt. Local anesthetics are divided into various categories on the basis of regional differences in pain perception. *Topical anesthetics* are anesthetics for superficial sites, e.g., mucous membranes or wound surfaces. *Infiltrative anesthetics* are injected into the skin or subcutaneous tissue. Finally, *nerve block anesthetics* are injected to anesthetize specific neuronal pathways; lumbar and epidural anesthesia are special forms of this type of anesthetic.

Mechanisms of Action. The sensory nerve axons are insulated by a lipoprotein sheath of myelin which is interrupted at sites called the nodes of Ranvier to speed up conduction of the nervous impulse. The effect of the local anesthetics on the sensory nerve endings is not specific. However, different excitable structures have varying sensitivities. Several hypotheses have been proposed to explain the molecular mechanism of the local anesthetic action of clinically-used agents. All local anesthetics inhibit the rapid influx of sodium ions into the cell which normally occurs during passage of a nerve impulse. Some substances bind to a specific binding site in the Na^+ channel which can only be reached from the inner side of the nerve cell membrane. This group of anesthetics includes elongated quaternary ammonium compounds that bear a lipophilic ring. Other uncharged substances of variable chemical structure and low polarity are integrated into (i.e., infiltrate) the membrane, without binding to a specific receptor, and disturb the integrity of the Na^+ channel. Basic local anesthetics act by both of these mechanisms, but the predominant mechanism is the reaction with the binding site in the Na^+ channel. In order for the local anesthetics to reach the receptor, they first have to diffuse through the cell membrane in the nonprotonated state. After passing through the cell membrane the agents generally return to their active protonated state, dependent upon the pK value of the compound and the intracellular pH [4–6].

An ideal local anesthetic has to induce anesthesia sufficiently rapidly in a confined region for a sufficiently long time. Adverse side effects (such as excitation of the central nervous system, inhibition of transmission of nervous impulses to muscle and at the synapse, influences on heart function and the circulatory system, damage to nervous tissue, and irritation of other tissues) as well as hypersensitivity reactions and allergies should be reduced to a minimal level.

10.1002/14356007.a15_415

Furthermore, a minimal absorption rate of the compound should be coupled with minimal toxicity. The active agent must be sufficiently stable and possess sufficient water solubility to allow preparation of a ready-for-use solution. The compound should not be too acidic or too alkaline, should be stable on sterilization, and should not decompose when stored for longer periods. Once the substance has been transported from the site of application into the bloodstream and organs, it should also be rapidly degraded into nontoxic metabolites and excreted.

Historical Aspects. The development of local anesthetics began in the second half of the 19th century with the discovery and use of the plant alkaloid cocaine. Initially cocaine was used as a topical anesthetic and nerve blocking agent. It is, however, now only used for special topical anesthesia of the eye, mainly due to its serious adverse side effects but also because of its low stability. Even before the structure of cocaine had been elucidated, efforts were made to modify cocaine and develop substances with a similar local anesthetic effect but without the drawbacks of cocaine. After various cocaine derivatives (e.g., psicaine, tropacaine, and encaine) had been prepared, the substituted benzoates of various alcohols, especially basic alcohols, were discovered. The major breakthrough occurred in 1904 when EINHORN and UHLFELDER synthesized procaine. With the discovery of procaine the systematic search for synthetic local anesthetics began. Procaine served as the first high-quality product and standard; all of its constituent parts were subsequently modified leading to the discovery of substances with local anesthetic action that displayed a variety of chemical structures. Simple relationships between structure and activity were also investigated [7–9].

Structure. The majority of the compounds now used as local anesthetics share three structural characteristics that will be illustrated with procaine:

The *aromatic residue* (heterocyclic compounds are, however, also effective) confers a sufficient degree of lipid solubility to the molecule. In addition to −CO−O−, the *electronegative bridging group* can also be −CO−S−, −CO−NH−, −CO−, −O−, −NHCO−, or −NHCOO. It usually consists of 1 – 3 carbon atoms which may have alkyl substituents. The *amino group* often has two alkyl substituents (C_1–C_4), which can be joined together to form (substituted) piperidine or morpholine. Occasionally, only one alkyl group (C_1–C_6) is present. According to Löfgren's rule, the amino group represents the hydrophilic and the aromatic residue the lipophilic portion of the compound. The very small number of nitrogen-free local anesthetics (e.g., polydocanol) can also be incorporated into this model:

The above model is a prerequisite for a potential local anesthetic effect. However, many compounds fit this model, but have no or only minimal local anesthetic action. A useful local anesthetic is produced only when it has a favorable combination of important physicochemical characteristics such as solubility, rate of diffusion, basicity, degradability, and partition coefficient.

This article describes the most important local anesthetics but does not evaluate their absolute efficacy. Instead a review of the most commonly used or historically important compounds is given.

2. Benzoates

The majority of synthetic local anesthetics are basic esters of 4-aminobenzoic acid (or 2- or 3-aminobenzoic acid):

Active compounds were created by modification of the aminoalcohol R^1, insertion of a further substituent R^2 into the phenyl core, alkylation of the amino group $-NHR^3$, and even elimination of the $-NHR^3$ group.

2.1. 4-Aminobenzoates

In 1890 Ritsert had already recognized the good local anesthetic action of ethyl 4-aminobenzoate. Two 4-aminobenzoates which still have a certain degree of importance are benzocaine and butamben.

Benzocaine [*94-09-7*], ethyl 4-aminobenzoate, $C_9H_{15}NO_2$, M_r 165.2, *mp* 88 – 90 °C.

Benzocaine is produced by reduction of ethyl 4-nitrobenzoate with iron [10]. It is used as a surface anesthetic.
Trade Names. Anaesthesin (Ritsert, Germany); Hurricaine (Beutlich, USA).

Butamben [*94-25-7*], *n*-butyl 4-aminobenzoate, $C_{11}H_{15}NO_2$, M_r 193.2, *mp* 57 – 59 °C.

Butamben is produced by the esterification of 4-nitrobenzoyl chloride with *n*-butanol and reduction of the resulting nitroester. Butamben is available in the United States as a surface anesthetic in the form of a picrate.
Trade Name. Butesine (Abbott, USA).

2.2. Basic Benzoates and Aminobenzoates

While searching for compounds with a high water solubility, A. Einhorn and E. Uhlfelder in 1904 synthesized the diethylaminoethyl ester of 4-aminobenzoic acid, also known as procaine. Procaine's high water solubility, tolerance, and stability made it the standard anesthetic for many decades, even though it produced a relatively low level of topical anesthesia. Many similar substances with a greater potency and broader spectrum of use were subsequently marketed. Because of these new products other particularly effective agents are now available for special anesthesias. However for infiltration anesthesia, procaine remained the most widely used product for a long period of time.

2.2.1. Basic Benzoates

Piperocaine hydrochloride [*533-28-8*], 3-(2-methylpiperidino)propyl benzoate hydrochloride, $C_{16}H_{23}NO_2{\cdot}HCl$, M_r 297.83, *mp* 172 – 175 °C.

The compound is produced by esterifying benzoyl chloride with 3-chloropropanol and subsequent reaction of the ester with 2-methylpiperidine [11]. Piperocaine is used as a topical anesthetic and a nerve block agent.
Trade Name. Metycaine (Lilly, USA).

2.2.2. Basic Aminobenzoates

Procaine hydrochloride [*51-05-8*], 2-diethyl-aminoethyl 4-aminobenzoate monohydrochloride, $C_{13}H_{20}N_2O_2{\cdot}HCl$, M_r 272.77, *mp* 154 – 157 °C.

The compound is prepared by reacting benzocaine and 2-diethylaminoethanol in the presence of catalytic amounts of sodium and simultaneous removal of the nascent ethanol by distillation [12]. Procaine is employed as an infiltration anesthetic and nerve block agent.
Trade Names. Novocain (Hoechst, Germany); Novocain (Winthrop Pharmaceuticals, USA).

Chloroprocaine hydrochloride [*3858-89-7*], 2-diethylaminoethyl 4-amino-2-chlorobenzoate monohydrochloride, $C_{13}H_{19}ClN_2O_2{\cdot}HCl$, M_r 307.22, *mp* 176 – 178 °C.

The compound is synthesized by esterification of 4-amino-2-chlorobenzoic acid with 2-diethylaminoethanol and subsequent transformation to the hydrochloride form [13]. Chloroprocaine is used as a nerve block agent and infiltration anesthetic.
Trade Name. Nesacaine (Astra Chemicals, USA).

Oxybuprocaine hydrochloride [*5987-82-6*], 2-diethylaminoethyl 4-amino-3-butoxybenzoate monohydrochloride, $C_{17}H_{28}N_2O_3{\cdot}HCl$, M_r 344.88, *mp* 157 – 160 °C.

This compound is produced by transesterification of ethyl 3-butoxy-4-aminobenzoate with 2-diethylaminoethanol and subsequent transformation to the hydrochloride form [14]. Oxybuprocaine is used as a topical ocular, nasal, and otic (aural) anesthetic.
Trade Names. Novesine Wander (Wander Pharma, Germany); combined with sodium fluorescein in Fluren (Barnes Hind, USA).

Proxymetacaine hydrochloride [*5875-06-9*], 2-diethylaminoethyl 3-amino-4-propoxybenzoate monohydrochloride, $C_{16}H_{26}N_2O_3{\cdot}HCl$, M_r 330.85, *mp* 178 – 185 °C.

The starting material for the synthesis of this compound is 4-hydroxy-3-nitrobenzoic acid which is converted to 3-nitro-4-propoxybenzoic acid in a two-step process. The latter is esterified with 2-diethylaminoethyl chloride, the nitroester is reduced, and the compound converted to the hydrochloride form with hydrochloric acid [15]. Proxymetacaine is used as a surface anesthetic in ophthalmology.
Trade Names. Proparakain (Ursapharma, FRG); Ophthaine (Squibb, USA).

Tetracaine hydrochloride [*136-47-0*], 2-dimethylaminoethyl 4-butylaminobenzoate monohydrochloride, $C_{15}H_{24}N_2O_2{\cdot}HCl$, M_r 300.83, *mp* 134 – 148 °C (three polymorphic modifications 134, 139, 148 °C).

This compound is synthesized by esterification of 4-butylaminobenzoic acid with 2-dimethylaminoethanol [16]. It is used as a nerve block agent and as a topical anesthetic.
Trade Names. Pantocain, Gingicain (Hoechst, Germany); Pantocaine (Winthrop Pharmaceuticals, USA).

3. Carboxylic Acid Amides

Several carboxylic acid amides are local anesthetics, especially the anilides of basically substituted aliphatic fatty acids and several *N*-substituted pipecolic acids. Aromatic carboxylic acid amides are of less importance, with the exception of cinchocaine (a basic amide of a heterocyclic carboxylic acid) and oxetacaine (an aliphatic acid amide).

3.1. Carboxylic Acid Anilides

Prior to the discovery of procaine EINHORN and OPPENHEIMER synthesized a series of base-substituted anilides and tested their local anesthetic effects. Nirvanin (Hoechst) can be considered the parent molecule of this group of compounds:

As a result of local adverse reactions this substance was only used for a short time therapeutically. It was not until 1937 that ERDTMANN and LÖFGREN resumed research into this group of compounds [17]. Several valuable derivatives were discovered which are described below. They produce rapid and long-lasting, deep local anesthesia with minimal toxicity, good tissue tolerance, and a high stability. Acid anilide compounds are consequently the most important and most widely used group of local anesthetics.

Lidocaine hydrochloride [*73-78-9*], 2-diethyl-amino-*N*-(2,6-dimethylphenyl)acetamide hydrochloride, $C_{14}H_{22}N_2O{\cdot}HCl$, M_r 270.82, *mp* 127–128 °C, as monohydrate [*6108-05-7*], M_r 288.82, *mp* 77–78 °C.

This compound is synthesized by reacting 2,6-dimethylaniline with chloroacetyl chloride in glacial acetic acid and adding sodium acetate. The product (chloroacetyl-2,6-dimethylanilide) is boiled with diethylamine in an inert solvent (e.g., benzene) [18]. The hydrochloride crystallizes with one molecule of water which can be removed by careful drying.

Lidocaine is used as an infiltration and surface anesthetic, as a nerve block agent, and as an antiarrhythmic agent after heart attacks.
Trade Name. Xylocain(e) (Astra Chemicals, Germany and USA).

Prilocaine hydrochloride [*1786-81-8*], *N*-(2-methylphenyl)-2-(propylamino)propanamidemonohydrochloride, $C_{13}H_{20}N_2O{\cdot}HCl$, M_r 256.77, *mp* 167–168 °C.

Prilocaine is synthesized by reacting 2-aminotoluene with 2-bromopropionyl chloride and then with *n*-propylamine [19].
Trade Names. Xylonest (Astra, Germany); Citanest (Astra, USA).

Mepivacaine hydrochloride [*16452-56-5*], *N*-(2,6-dimethylphenyl)-1-methyl-2-piperidinecarboxamide monohydrochloride, $C_{15}H_{22}N_2O{\cdot}HCl$, M_r 282.81, *mp* 262–264 °C.

Mepivacaine is prepared either by reacting 2,6-dimethylaniline magnesium bromide with ethyl-1-methyl-2-piperidine carboxylate or by hydrogenation and subsequent *N*-methylation of pipecolic acid 2,6-xylidide [20], [21]. It is used as an infiltration anesthetic and nerve block agent.
Trade Names. Scandicain (Astra Chemicals, Germany); Carbocaine (Winthrop Pharmaceuticals, USA); Polocaine (Astra Chemicals, USA).

Bupivacaine hydrochloride [*18010-40-7*], 1-*n*-butyl-*N*-(2,6-dimethylphenyl)-2-piperidinecarboxamide monohydrochloride, $C_{18}H_{28}N_2O{\cdot}HCl$, M_r 324.9, *mp* 255–256 °C.

The compound is prepared by reacting 2,6-dimethylaniline with piperidine-2-carboxylic acid chloride hydrochloride. The resulting anilide is alkylated with 1-butylbromide and converted to the hydrochloride [22]. Bupivacaine is used as an infiltration anesthetic and as a nerve block agent especially for long duration blocks.
Trade Names. Carbostesin (Astra Chemicals, Germany); Marcaine (Winthrop Pharmaceuticals, USA).

Ropivacaine monohydrate [*132112–35–7*], (*S*)-(−)-1-propyl-*N*-(2,6-dimethylphenyl)-2-piperidinecarboxamide hydrochloride monohydrate, $C_{17}H_{26}N_2O{\cdot}HCl{\cdot}H_2O$, M_r 328.13, *mp* 269.5 – 270.6 °C, $[\alpha]_D^{20} = -7.28°$ ($c = 2$, H_2O).

The compound is synthesized by reacting L-pipecolic acid with 2,6-xylidine and subsequent alkylation with 1-propylbromide [23]. Finally it is converted to the hydrochloride monohydrate [24].

Ropivacaine is an *N*-alkylpipecolic acid amide like mepivacaine and bupivacaine. However, in the case of ropivacaine not the racemate but only the (*S*)-enantiomer is used as a long-acting anesthetic. The indications are the same as for bupivacaine.
Trade Name. Naropin (Astra, Sweden).

Etidocaine hydrochloride [*36637-19-1*], *N*-(2,6-dimethylphenyl)-2-(ethylpropylamino) butanamide hydrochloride, $C_{17}H_{28}N_2O{\cdot}HCl$, M_r 312.9, *mp* 201 – 206 °C.

Etidocaine is synthesized by acylating 2,6-dimethylaniline with 2-bromobutyric acid. The bromine atom is replaced by iodine during boiling with potassium iodide in methanol. Reaction with *n*-propylamine yields the *n*-propylamino compound, which is then alkylated with diethyl sulfate [25]. Etidocaine is used as a long-acting infiltration anesthetic and nerve block agent.
Trade Names. Dur-Anest (Astra Chemicals, FRG); Duranest (Astra Chemicals, USA).

Butanilicaine hydrochloride [*6027-28-7*], *N*-(2-chloro-6-methylphenyl)-2-(butylamino) acetamide hydrochloride, $C_{13}H_{19}ClN_2O{\cdot}HCl$, M_r 291.2, *mp* 232 °C.

This compound is produced by reacting 2-chloro-6-methylaniline with chloroacetyl chloride. Subsequent reaction with excess *n*-butylamine yields the base which is converted to the hydrochloride form by reaction with hydrochloric acid [26]. Butanilicaine is used as an infiltration anesthetic and nerve block agent.
Trade Name. Hostacain (Hoechst, Germany).

Articaine hydrochloride [*23964-57-0*], 4-methyl-3-[2-(*n*-propylamino)propionamido]-2-thiophenecarboxylic acid methyl ester hydrochloride, $C_{13}H_{20}N_2O_3S{\cdot}HCl$, M_r 320.8, *mp* 175 – 176 °C.

The compound is synthesized by reacting methyl 3-amino-4-methylthiophene-2-carboxylate with 2-bromopropionyl chloride and then with *n*-propylamine [27]. Articaine is used as an infiltration anesthetic and a nerve block agent.
Trade Name. Ultracain (Hoechst, Germany).

3.2. Amides of Heterocyclic Carboxylic Acids

Cinchocaine hydrochloride [*61-12-1*], 2-butoxy-*N*-[2-(diethylamino)ethyl]-4-quinolinecarboxamide monohydrochloride,

$C_{20}H_{29}N_3O_2 \cdot HCl$, M_r 379.93, *mp* 95 – 100 °C (decomp.).

This compound is synthesized by rearrangement of *N*-acetylisatin with sodium hydroxide to form 2-hydroxyquinoline-4-carboxylic acid. Reaction with phosphorus pentachloride gives the acid chloride, whereby chlorine replaces the hydroxy group. The basic amide is then obtained on reaction with 2-diethylaminoethylamine. Addition of sodium butoxide gives the cinchocaine base [28], which is used as a topical anesthetic.
Trade Name. Nupercainal (Ciba-Geigy, USA).

3.3. Amides of Aliphatic Carboxylic Acids

Oxetacaine [*126-27-2*],2,2′-[(2-hydroxyethyl)- imino]bis[*N*-(1,1-dimethyl-2-phenylethyl)-*N*-methylacetamide], $C_{28}H_{41}N_3O_3$, M_r 467.65, *mp* 104 –104.5 °C.

Oxetacaine is produced by reacting 1-phenyl-2,2-dimethylaminopropane with chloroacetyl chloride and then with 2-aminoethanol [29]. It is the most effective topical anesthetic in clinical use and is mainly employed for anesthesia of the gastric mucosa.
Trade Name. Tepilta suspension (Wyeth Pharma, Germany).

4. Basic Ketones and Ethers

In addition to the basic acid amides and acid anilides, extensive studies have also been performed on basic ketones and ethers. Effective local anesthetics were also found in these families of compounds; several examples are described below.

4.1. Basic Ketones

Propipocaine hydrochloride [*1155-49-3*], 1-(4-propoxyphenyl)-3-(1-piperidinyl)-1-propanone hydrochloride, $C_{17}H_{25}NO_2 \cdot HCl$, M_r 311.9, *mp* 166 °C.

The compound is prepared by Mannich condensation of 4-propoxyacetophenone with formaldehyde and piperidine [30]. It is used as a topical anesthetic.
Trade Name. Anaesthesie (Ankerpharm, Germany).

Dyclonine hydrochloride [*536-43-6*], 1-(4-butoxyphenyl)-3-(1-piperidinyl)-1-propanone hydrochloride, $C_{18}H_{27}NO_2 \cdot HCl$, M_r 325.88, *mp* 175 – 176 °C.

This compound is synthesized from 4-butoxyacetophenone analogously to Propipocaine [31]. It is used as a topical anesthetic.
Trade Name. Dyclone (Astra Chemicals, USA).

4.2. Basic Ethers

Pramocaine hydrochloride [*637-58-1*], 4-[3-(4-butoxyphenoxy)propyl]morpholine hydrochloride, $C_{17}H_{27}NO_3 \cdot HCl$, M_r 329.87, *mp* 181 – 183 °C.

The compound is produced by alkylation of 4-butoxyphenol with 3-chloro-1-morpholinopropane [32]. It is used as a topical anesthetic.
Trade Name. Tronothane (Abott, USA).

Fomocaine hydrochloride [*56583-43-8*], 4-[3-(α-phenoxy-*p*-tolyl)propylmorpholine hydrochloride, $C_{20}H_{25}NO_2 \cdot HCl$, M_r 347.9, *mp* 171 – 173 °C.

Fomocaine is produced by chloromethylation of phenylpropyl chloride, followed by synthesis of the phenolic ether and conversion of the ether to a base with morpholine [33]. It is used as a topical anesthetic.
Trade Name. Myko Posterine (Kade, Germany).

Quinisocaine hydrochloride [*2773-92-4*], 2-[(3-butyl-1-isoquinolinyl)oxy]-*N,N*-dimethylethanamine monohydrochloride, $C_{17}H_{24}N_2O \cdot HCl$, M_r 308.85, *mp* 144 – 148 °C.

The parent substance for this compound is phthalaldehydic acid which is converted to 1,4-dihydroxy-3-butyl-3,4-dihydroisoquinoline by condensation with nitropentane, catalytic hydrogenation, and rearrangement with alkali. Reaction with phosphorus oxychloride results in the elimination of water and the production of 1-chloro-3-butyl-isoquinoline. The ether is obtained on addition of sodium 2-dimethylaminoethoxide [34]. It is used as a topical anesthetic.
Trade Names. Quotane (Smith, Kline & French, USA); Isochinol (Chemipharm, Germany).

5. Nitrogen-Free Local Anesthetics

The only nitrogen-free local anesthetics of any importance are alcohols.

Polydocanol [*3055-99-0*], poly(ethylene glycol)monododecyl ether, ca. $C_{30}H_{62}O_{10}$, $C_{12}H_{25}-O-(CH_2CH_2)_{8-9}-CH_2CH_2OH$ is synthesized by heating ethylene oxide with dodecanol at 180 °C in the presence of catalytic amounts of sodium hydroxide [35]. It is used as a topical anesthetic for phlebosclerosation.
Trade Name. Aethoxysklerol (Kreussler, Germany).

Benzyl Alcohol [*100-51-6*], C_7H_8O, M_r 108.14, *bp* 207.4 °C.

For production and properties see → Benzyl Alcohol. It is a constituent of various combination preparations used for topical anesthesia (prolongation of action).

1. Introduction

The most important function of lubricants is the reduction of friction and wear. Scientific research has shown that 0.4 % of gross domestic product could be saved in terms of energy in Western industrialized countries if current tribological knowledge, i.e., the science of friction, wear, and lubrication, was just applied to lubricated processes.

Apart from important applications in internal combustion engines, vehicle and industrial gearboxes, compressors, turbines, or hydraulic systems, there are a vast number of other applications which mostly require specifically tailored

lubricants. Between 5000 and 10 000 different lubricant formulations are necessary to satisfy more than 90 % of all lubricant applications.

Mineral oil components continue to form the quantitatively most important foundation of lubricants. Petrochemical components and increasingly derivatives of natural, harvestable raw materials from the oleo-chemical industry are finding increasing acceptance because of their environmental compatibility and some technical advantages

Lubricants today are classified into two major groups: automotive lubricants and industrial lubricants. Industrial lubricants can be sub-divided into industrial oils and industrial specialties; i.e., greases, metalworking lubricants, and solid lubricant films.

Process oils are often included in lubricant statistics. These are oils which are included as raw materials in processes, but above all as plasticizers for the rubber industry. Process oil's only link with lubricants is that they are mineral oil products resulting from the refining of base oils but they often distort lubricant consumption figures. They will not be covered in this book. However, to provide a degree of comparison, they have been included in the following lubricant statistics.

Apart from the most common lube oils, the many thousands of lubricant applications necessitate a diverse number of systems which is seldom equaled in other product groups.

The group next to oils are emulsions, which as oil-in-water emulsions are central to water-miscible cutting fluids (Chap. 12) and rolling emulsions. In these cases, the lubricant manufacturer normally supplies a concentrate which is mixed with water locally to form an emulsion. The concentration of these emulsions with water are generally between 1 and 10 %. The annual consumption of such emulsions in industrialized countries is about the same as all other lubricants together. From this point of view, the volumetric proportion of these products (as concentrates) is significantly under-rated in lubricant statistics.

The next group of lubricant systems are water-in-oil emulsions (invert emulsions). Their most important application is in metal forming. These products are supplied ready-to-use or as dilutable concentrates. Fire resistant HFB fluids are designed as water-in-oil emulsions too.

In some special cases, oil-in-oil emulsions are developed as lubricants and these are primarily used in the field of metalworking.

Water-based solutions in the form of non-dispersed systems are sometimes used in chip-forming metalworking operations.

Greases (Chap. 14) are complex systems consisting of base oils and thickeners based on soaps or other organic or inorganic substances. They are available in semiliquid form (semifluid greases) through to solid blocks (block greases). Special equipment is required for their production (grease-making plants). A group of products closely related to greases are pastes.

Solid lubricant suspensions normally contain solid lubricants in stable suspension in a fluid such as water or oil. These products are often used in forging and extrusion and other metalworking processes. Solid lubricant films can also be applied as suspensions in a carrier fluid which evaporates before the lubricant has to function.

Solid lubricant powders can be applied directly to specially-prepared surfaces.

In the case of dry-film lubricants (Chap. 15), solid lubricants are dispersed in resin matrices. Dry-film lubricants are formed when the solvent (principally water or hydrocarbons) evaporates.

Molten salts or glass powder are used for hot forming processes such as extrusion. These are normally supplied as dry powders and develop lubricity when they melt on the hot surface of the metal.

Polymer films are used when special surface protection is required in addition to lubricity (e.g., the pressing of stainless steel panels). Together with greases, these products are also used to some extent in the construction industry.

2. Lubricants in the Tribological System

Tribology (derived from the Greek tribein, or tribos meaning rubbing) is the science of friction, wear, and lubrication. Although the use of lubricants is as old as mankind, scientific focus on lubricants and lubrication technology is relatively new. The term tribology was first introduced in 1966 and has been used globally to describe this far-reaching field of activity since 1985. Even though efforts had been made since the 16th century to describe the whole phenomenon of fric-

Figure 1. Sliding and rolling

tion scientifically (Leonardo da Vinci, Amontons, Coulomb), the work always concentrated on single aspects and lubricants were not even considered. Some research work performed up to the early 1970s totally ignored the chemical processes which take place in lubricated friction processes.

The tribological system (commonly referred to as the tribosystem) consists of four elements: the twocontacting partners, the interface between the two and the medium in the interface and the environment [52]. In lubricated bearings the lubricant is located in this gap. In plain bearings, the material pair are the shaft and the bearing shells; in combustion engines they are the piston rings and the cylinder wall or the camshaft lobes and the tappets and in metalworking, the tool and the workpiece.

The variables are the type of movement, the forces involved, temperature, speed, and duration of the stress. Tribometric parameters – such as friction, wear, and temperature data – can be gathered from the stress area. Tribological stress is the result of numerous criteria of surface and contact geometry, surface loading, or lubricant thickness. Tribological processes can occur in the contact area between two friction partners – which can be physical, physicochemical (e.g., adsorption, desorption), or chemical in nature (tribochemistry).

2.1. Friction

2.1.1. Types of Friction

Friction is the mechanical force which resists movement (dynamic or kinetic friction) or hinders movement (static friction) between sliding or rolling surfaces. These types of friction are also called external friction.

Internal friction results from the friction between lubricant molecules; this is described as viscosity (Chap. 3).

The causes of external friction are, above all, the microscopic contact points between two slid-

Figure 2. 'Wälzreibung', mixing of rolling and sliding motions.
a) Rolling in metal forming; v_1, initial speed of the sheet metal; v_2, final speed of the sheet metal; v_3, speed of the roller; v_r, speed difference in the roll gap (sliding part); N, neutral point (non-slip point, pure rolling)
b) Engagement of gear teeth, 1, 2, 4. high sliding/rolling ratio; 3. pitch circle (pure rolling, no slip)

ing surfaces; these cause adhesion, material deformation, and grooving. Energy which is lost as friction can be measured as heat and/or mechanical vibration. Lubricants should reduce or avoid the micro-contact which causes external friction.

Sliding friction occurs in a pure sliding motion with no rolling and no spin (Fig. 1).

The coefficient of friction μ is defined as the dimensionless ratio of the friction force F and the normal force N. The proportionality between normal force and frictional force is often given in dry and boundary friction conditions but not in fluid-film lubrication.

Rolling friction is the friction generated by rolling contact. In roller bearings, rolling friction mainly occurs between the rolling elements and the raceways, whereas sliding friction occurs between the rolling elements and the cage. The main cause of friction in roller bearings is sliding in the contact zones between the rolling elements and the raceways. It is also influenced by the geometry of the contacting surfaces and

the deformation of the contacting elements. In addition, sliding also occurs between the cage pockets and the rolling elements.

If rolling motion and sliding motion combine to any significant extent, as for gear tooth meshing, special terminology has been created. The word 'Wälzreibung' which is derived from 'Wälzen' (rolling, e.g., steel rolling) is used in Germany. Situations in which a high sliding/rolling ratio occur require totally different lubrication than does pure sliding. Figure 2 shows this 'rolling friction' during rolling and during gear meshing.

Static Friction. The static coefficient of friction is defined as the coefficient of friction corresponding to the maximum force that must be overcome to initiate macroscopic motion between two bodies (ASTM).

Kinetic Friction. Different from static friction, kinetic friction occurs under conditions of relative motion. ASTM defines the kinetic coefficient of friction as the coefficient under conditions of macroscopic relative motion of two bodies. The kinetic coefficient of friction (dynamic coefficient of friction) is usually somewhat smaller than the static coefficient of friction.

Stick – slip is a special form of friction which often results from very slow sliding movements when the friction partners are connected to a system which can vibrate. The process is influenced by the dependence of the coefficient of sliding friction on speed. This generally occurs when the static coefficient of friction (f_{stat}) is larger than the dynamic coefficient of friction (f_{dyn}). Stick – slip is normally encountered with machine tools which operate with slow feeds. Stick – slip can cause chatter marks on components.

2.1.2. Friction and Lubrication Conditions

In tribological systems, different forms of contact can exist between contacting partners.

Solid friction (dry friction) occurs when two solids have direct contact with each other without a separating layer. If conventional materials are involved, the coefficients of friction and wear rates are high. Lubrication technology attempts to eliminate this condition.

Boundary Friction. The contacting surfaces are covered with a molecular layer of a substance whose specific properties can significantly influence the friction and wear characteristics. Boundary friction layers are of great importance in practical applications when thick, long-lasting lubricant films to separate two surfaces are technically impossible. Boundary lubricating films are created from surface-active substances and their chemical reaction products. Adsorption, chemisorption, and tribochemical reactions also play significant roles.

Fluid Friction. In fluid friction, both surfaces are fully separated by a fluid lubricant film (full-film lubrication). This film is either formed hydrostatically or more commonly, hydrodynamically (Fig. 3). Liquid or fluid friction is caused by the frictional resistance, because of the rheological properties of fluids.

Figure 3. Hydrostatic lubrication as a form of fluid friction

If both surfaces are separated by a gas film, this is known as gas lubrication.

Mixed friction occurs when boundary friction combines with fluid friction. Machine elements which are normally hydrodynamically lubricated experience mixed friction when starting and stopping.

Solid lubricant friction occurs when solid lubricants are used (Chap. 15).

Stribeck Diagram. The friction or lubrication conditions between boundary and fluid friction are graphically illustrated by use of Stribeck diagrams (Fig. 4) [53]. These are based on the starting-up of a plain bearing whose shaft and bearing shells are, when stationary, separated only by a molecular lubricant layer. As the speed of revolution of the shaft increases (peripheral speed) a thicker hydrodynamic lubricant film is created what initially causes sporadic mixed friction but which, nevertheless, significantly reduces the coefficient of friction. As the speed continues to increase, a full, uninterrupted film is formed over the entire bearing faces; this sharply reduces the coefficient of friction. As speed increases, internal friction in the lubricating film adds to external friction. The curve passes a minimum coefficient of friction value and then increases, solely as a result of internal friction. The lubricant film thickness shown in Figure 4 depends on the friction and lubrication conditions including the surface roughness R.

Hydrodynamic Lubrication. In hydrodynamic lubrication the lubricant is pulled into the conical converging clearance by the rotation of the shaft. The created dynamic pressure carries the shaft.

On the basis of the Navier – Stokes theory of fluid mechanics, Reynolds created the basic formula for hydrodynamic lubrication in 1886. The application of the Reynolds' formula led to theoretical calculations on plain bearings. The only lubricant value was viscosity.

Elastohydrodynamic Lubrication (EHD Regime). Hydrodynamic calculation on lubricant films was extended to include the elastic deformation of contact faces (Hertzian contacts, Hertz's equations of elastic deformation) and the influence of pressure on viscosity (Chap. 3). This enables application of these elastohydrodynamic calculations to contact geometries other than that of plain bearings – e.g., those of roller bearings and gear teeth.

Figure 5 shows the elastic deformation of the ball and raceway of a ball bearing.

2.2. Wear (→ Abrasion and Erosion)

Wear is created by the processes of abrasion, adhesion, erosion, tribochemical reactions, and metal fatigue which are important to lubrication technology.

Types of Wear. There are several criteria which could be used to classify the different types of wear. For example, according to the types of (kinematic) friction which lead to wear (sliding wear, rolling wear, fretting wear), according to wear mechanisms (adhesive wear, abrasive wear, tribochemical wear) or according to the shape of the wear particle.

There is also highly specialized wear terminology for different lubricant applications; this is oriented to the geometry of the various bearing faces (e.g., clearance and crater wear in the field of chip-forming tools).

The Wear Process. Wear can be measured gravimetrically, volumetrically or in terms of area over a period of time or against increasing load. Uniformly decreasing wear which stabilizes at a very low level can be described as running-in wear. This can be controlled by the tribochemical reactions of the additives in the lubricants. Wear can occur at relatively constant speed and ultimately lead to the functional failure of the bearing. Wear at an increasing wear rate can lead to progressive wear. In time, the material damage caused by wear will also lead to the failure of a component.

Analysis of machine element failure as a result of wear and lubrication can be performed by use of practically oriented tests. Determination of the effect of different greases on the projected failure of roller bearings has become increasingly important.

3. Rheology of Lubricants

Consistency, flow properties, or viscosity in the case of oils, are key parameters to create lubrication efficiency and the application of lubricants.

3.1. Viscosity (→ Rheometry)

The measure of internal friction in a fluid is viscosity. Viscosity and its dimensions are best

Figure 4. Stribeck graph according to H. CZICHOS and K.-H. HABIG [53]
a) Boundary friction ($h \to 0$); b) Mixed film friction ($h \approx R$); c) Elastohydrodynamic lubrication ($h > R$); d) Hydrodynamic lubrication ($h >> R$)

explained with a model of parallel layers of fluid which could be viewed molecularly. If this packet of fluid layers is sheared (τ), the individual fluid layers are displaced in the direction of the shearing force. The upper layers move more rapidly than the lower layers because molecular forces act to resist movement between the layers. These forces create resistance to shearing and this resistance is given the term dynamic viscosity. The difference in velocity between two given fluid layers, related to their linear displacement, is referred to as shear rate S. This velocity gradient is proportional to the shear stress (τ). The proportionality constant η is called dynamic viscosity and has the unit Pa · s.

$$\tau = \eta \cdot S$$

The laboratory determination of viscosity in run-out or capillary tubes is influenced by the weight of the fluid. The relationship between dynamic viscosity and specific gravity is referred to as kinematic viscosity ν. The following unit analysis applies:

$$\nu = \frac{\eta}{\varrho}\left[\frac{\mathrm{Pa{\cdot}s}}{\mathrm{kg{\cdot}m^{-3}}}\right] \text{ or } \left[\frac{\mathrm{N{\cdot}s{\cdot}m^3}}{\mathrm{m^2{\cdot}kg}}\right] \text{ or } \left[\frac{\mathrm{kg{\cdot}m{\cdot}s^{-2}{\cdot}s{\cdot}m^3}}{\mathrm{m^2{\cdot}kg}}\right] \text{ or } \left[\frac{\mathrm{m^2}}{\mathrm{s}}\right] \left[\frac{\mathrm{mm^2}}{\mathrm{s}}\right] \text{ or (Centistoke)} \tag{3.1}$$

Fluids which display the above proportionality constant between shear stress and shear rate are referred to as Newtonian fluids, i.e., the viscosity of Newtonian fluids is independent of shear rate (→ Fluid Mechanics). Deviations from this Newtonian behavior are sometimes referred to as structural viscosity. Those viscosities are named as apparent viscosities.

Influence of Temperature on Viscosity ($V-T$ Behavior). The viscosity of all oils used for lubrication purposes drops significantly

Figure 5. Improvement of hydrodynamic lubrication clearance between two rollers by Hertzian deformation (elastohydrodynamic contact, EHD contact), pressure distribution in the Hertzian contact

when their temperature increases. In linear systems, this $V-T$ behavior is hyperbolic and the practical differentiation necessary in practice is difficult to replicate and the interpolation between two measured viscosities is also problematic. For these reasons, $V-T$ behavior has been allocated to a function which results in a straight-line graph if suitable coordinates are selected (Ubbelohde – Walter equation).

$$\log\log(\nu + C) = K - m \cdot \log T \tag{3.2}$$

In this double-logarithmic formula, C and K are constants, T is temperature in Kelvin and m is the $V-T$ line slope. Figure 6 show the linear and Ubbelohde – Walter double-logarithmic $V-T$ curves of three oils with significantly differing $V-T$ lines (naphthenic oil, paraffinic HC-II / Group III oil / Chap. 4) and a natural vegetable (rapeseed) oil.

The constant C for mineral oils in the $V-T$ equation is between 0.6 and 0.9.

The constant C only plays a minor role in the viscosity calculation, larger differences are only apparent at very low temperatures.

The Vogel – Cameron equation is used for the rapid, computer-based calculation of dynamic viscosity. The Vogel – Cameron viscosity – temperature equation is:

$$\eta = A \cdot \exp\left(\frac{B}{T + C}\right) \tag{3.3}$$

where A, B, and C are constants and T is again temperature in Kelvin.

The m value in the Ubbelohde – Walter equation which represents the double-logarithmic $V-T$ graph slope is sometimes used to characterize the $V-T$ behavior of oils. The m value for lubricant base oils is between 4.5 and 1.1 [54]. The smaller values apply to oils which are less affected by temperature.

Figure 6. $V-T$ behavior of various oils
A) Linear; B) Double-logarithmic
a) Paraffinic base oil; b) Naphthenic base oil; c) Rapeseed oil

Figure 7. Graphical illustration of viscosity index (VI)

$$m = \frac{\log\log(\nu_1 + 0.8) - \log\log(\nu_2 + 0.8)}{\log T_2 - \log T_1} \qquad (3.4.)$$

The viscosity – temperature constant (VTC) was introduced to better differentiate $V-T$ behavior when the influence of temperature is low.

$$VTC = \frac{\nu_{40} - \nu_{100}}{\nu_{40}} \qquad (3.5)$$

The evaluation of $V-T$ behavior at low temperatures according to Ubbelohde – Walter lines or other straight-line $V-T$ graphs often leads to inaccuracies. These dependencies do not apply to

base oils which can suffer thickening caused by crystallization of some components (e.g., paraffins) at low temperatures or those whose polymer molecules simulate viscosity effects at low temperatures.

Viscosity Index. The viscosity index *VI* is far more important for the description of viscosity – temperature behavior than the *m* value or the viscosity – temperature constant. This value was first introduced in the USA in 1928. It was based on the then greatest ($VI = 100$) and the smallest ($VI = 0$) temperature dependence of US base oils.

VI is graphically illustrated in Figure 7. Values over 100 are calculated as *VIE*.

Viscosity index is also defined in the most international standards.

Table 1 shows various $V-T$ characteristics for a number of oils.

Viscosity – Pressure Dependency. The significance of viscosity – pressure dependency ($V-p$ behavior) was, and still is, underestimated for numerous lubrication applications. $V-p$ behavior has become a part of the calculation of elastohydrodynamic lubricant films.

$V-p$ behavior can be described by the formula:

$$\eta_{\mathrm{P}} = \eta_1 \cdot \mathrm{e}^{\alpha(p-p_1)} \tag{3.6}$$

where η_{P} is the dynamic viscosity at a pressure p, η_0 is the dynamic viscosity at 1 bar and α is the viscosity – pressure coefficient:

$$\alpha = \frac{1}{\eta_{\mathrm{P}}} \cdot \left(\frac{\mathrm{d}\eta_{\mathrm{P}}}{\mathrm{d}p}\right)_{\mathrm{T}} \tag{3.7}$$

$V-p$ dependence is defined by the chemical structure of the substances with the steric geometry of the molecules being of particular significance.

Figure 8 and 9 show viscosity – pressure relationship for a number of oils with different chemical structures.

α can increase significantly with falling temperature which has an exponential effect on viscosity.

Viscosity – Shear Rate Relationship. The viscosity of Newtonian fluids is a constant (proportionality factor) between the shear force τ and the shear rate S and not dependent on shear rate. Lubricants which display a dependence on shear rate are known as non-Newtonian or fluids with structural viscosity.

Oils containing polymers with specific additives or thickeners and mineral oils at low temperatures (long-chain paraffin effects) display such structure-viscous behavior. At normal application temperatures, most major lubricant base oils such as hydrocarbon oils (mineral oil raffinates or synthetic hydrocarbons), synthetic esters and natural fatty oils can withstand very high shearing forces (e.g., $10^9\ \mathrm{s}^{-1}$) as found in highly loaded machine elements (e.g., gearboxes) and are independent of shear rate.

Engine oils containing polymer $V-T$ improvers (Chap. 8) or polymer ash-free dispersants display structural – viscosity effects at low and high temperatures.

While the reduction in viscosity caused by the shearing of structure-viscous fluids is reversible, polymer-based oils can suffer a permanent reduction in viscosity. In these cases, the shearing forces lead to a mechanical change or reduction in the size of the polymer molecules so that their desired effects are minimized. These effects have been observed, in particular, with multigrade engine oils and high-*VI* hydraulic oils.

3.2. Special Rheological Effects

Apart from the above-described effects, lubricants are subject to further rheological phenomena and in particular, colloidal systems consisting of solid or fluid dispersions (solid dispersions or emulsions).

Even small mechanical loading such as vigorous stirring can cause a system to change completely, e.g., pasty systems can break down into low-viscosity systems (Fig. 10). If continuous mechanical load causes apparent viscosity to fall over time and the original viscosity is restored after a certain rest period, such fluids are called thixotropic. This effect is used for sheet forming lubricants (Chap. 13).

Time-based viscosity changes can also be caused by the separation of colloidal particles such as paraffins from mineral base oils, or additives during the storage of lubricants. This undesirable effect can occur during the cooling

Figure 8. Viscosity – pressure relationship of various oils
1) Aromatic oil; 2) Naphthenic oil; 3) Paraffinic oil; 4) Biodegradable polyol ester

Table 1. Various $V-T$ characteristics for several oils [54]

	Kinematic viscosity mm^2/s		Viscosity index	*m* Constant	Viscosity temperature constant
	40 °C	100 °C	(*VI*)		(*VTC*)
Naphthenic spindle oil	30	4.24	40	4.05	0.847
Paraffinic spindle oil	30	5.23	105	3.68	0.819
Medium solvent extract	120	8.0	−50	4.51	0.939
Medium polyalkylene glycol	120	20.9	200	2.53	0.826
Medium silicone oil	120	50.0	424	1.14	0.583
Multigrade motor oil (SAE 10W-30)	70	11.1	165	2.82	0.841
Ester oil	30	5.81	140	3.40	0.806

phase following production or by long-term storage at low temperatures. This separation process can also be independent of temperature and be caused by the solubility status of additives in the base oils.

Greases. The rheological description of greases is also complex because of their complex system structure (fluids, soap thickeners, solid thickeners, additives, Chap. 14). The mathematical description of apparent viscosity has not gained general acceptance in practice.

At lower shear loads, greases behave similarly to structure-viscous substances but at high shear loads, like Newtonian base oils.

3.3. Viscosity Grades

To simplify the classification of lubricants according to their application, viscosity grades were introduced which are now internationally accepted. ISO viscosity grades apply to industrial lubricants while Society of Automitive Engineers (SAE) classifications apply to automotive engine and gear oils (see Fig. 11).

ISO Viscosity Grades. 18 viscosity grades are laid down in the ISO standard 3448. Over the range from 2 to 2500 mm^2/s, these are the international standard number series E6 rounded to whole numbers when the 6 numerals correspond to one power of ten (the first and fourth power of 10 are reduced). The viscosity grades were also

Figure 9. Increase of the viscosity – pressure coefficient with falling temperature according to H. HOLLAND [55]

Figure 10. Various lubricant structures (a, b, c) with high sensitivity against shear stress

adopted into or added to national standards such as ASTM or DIN.

Viscosity grades are not used for all industrial lubricants. Particularly oils for chip-forming and chip-less metalworking processes are not classified in this way.

Apart from the viscosity grades, ISO 3448 defines tolerances as well as median viscosities.

Other Viscosity Grades.

Engine Oils. To define the viscosity of engine oils, two or three viscosity thresholds were selected to define flow properties at low temperatures and to define a minimum viscosity at high temperatures. Maximum viscosity at low temperature should ensure the rapid oil circulation to all lubrication points and permit a sufficiently higher cranking speed for starting and the minimum viscosity at 100 °C should ensure that adequate lubrication of the bearings occurs at high temperatures. The classification system was introduced by the SAE together with the American Society for Testing and Materials (ASTM) and is used throughout the world. Low temperature viscosity is measured as dynamic viscosity with a specially constructed rotational viscosimeter (cold cranking simulator) at low shear rates (Chaps. 8 and 11).

Automotive Gear Oils. Specific SAE viscosity grades have been created for automotive gearbox, axle and differential oils. Compared with engine oils, the low temperature behavior of these oils is more heavily weighted.

Figure 11. Comparison of viscosity grades for various applications

Industrial Gear Oils. AGMA (American Gear Manufacturers Association) defines nine viscosity ranges for industrial gear oils.

Viscosity Grades for Base Oils. Mineral base oils are traditionally classified according to Saybolt Universal Seconds (SUS). A 150 N base oil shows a viscosity of 150 SUS at 100 °F.

4. Base Oils

In terms of volume, base oils are the most important components of lubricants, they account for more than 95 % of lubricant formulations. There are lubricant families (e.g., some hydraulic and compressor oils) in which chemical additives

only account for 1 % while the remaining 99 % are base oils. On the other hand, other lubricants (e.g., some metalworking fluids, greases, or gear lubricants) can contain up to 30 % additives.

4.1. Historical Review and Outlook

Although the most important requirement of base oils in the 1950s was the correct viscosity and the absence of acidic components, base oils in the 1960s were downgraded to solvents or carriers for additives in the euphoria surrounding chemical additives. In the 1970s, there was a realization that some synthetic fluids with uniform basic chemical structures offered performance superior to that of mineral base oils. At that time, the considerably higher price of these products hindered their market acceptance. In the 1980s however, lower-price, quasi-synthetic hydrocracked oils were introduced in Western Europe which closely matched the properties of synthetic hydrocarbons (Shell, BP, Fuchs). In the 1990s, base oil developments were influenced by the ever-increasing demands on lubricant performance, and by environmental and health and safety criteria. This led to chemically pure oils such as hydrocracked products, polyalphaolefins and esters gaining acceptance. Natural fatty oils, particularly their oleochemical derivatives, have experienced a renaissance because of their technical characteristics but, above all, because of their rapid biodegradability.

The trend towards ever-greater performance and even better environmental compatibility will continue in the first decade of the new millennium. The significantly higher price of the new lubricants, which will be increasingly characterized by their base oils and less so by their chemical additives, will probably be accepted by users who will benefit from long product life and lower overall system costs. In Western Europe in 1998 [56], about 10 wt % of base oils were synthetic products (including Group 3 hydrocracked oils (Section 16.1). These, however, represented about 40 % of base oil value. In Germany, furthermore, ca. 5 % of lubricant base oils were rapidly biodegradable (natural and synthetic) esters in 1999. It is safe to assume that in Western Europe at least, synthetic and quasi-synthetic oils will in terms of value, have overtaken traditional mineral base oils by the year 2005.

4.2. Chemical Characterization of Mineral Base Oils

Crude oil generally consists of many thousands of single components and these are reflected in the processing of each fraction. Thus, mineral oil fractions have always been characterized by defining their technical properties or to identify and quantitatively determine groups of components with similar chemical character. Advanced physicochemical methods are, however, increasingly being used in routine testing.

Rough Chemical Characterization.
Viscosity – Gravity Constant (VGC). This value enables only rough chemical characterization of oils. Values near 0.800 indicate paraffinic character whereas values near to 1.000 point to a majority of aromatic structure (ASTM 2501-91)
Aniline Point. The aniline point is also used to characterize the hydrocarbon structure of mineral oils (see Section 16.2.8).

Carbon Distribution. The most important means of analysis for characterization of mineral oil hydrocarbons is the determination of carbon in terms of its three categories of chemical bond – aromatic (C_A), naphthenic (C_N), and paraffinic (C_P).

N – D – M analysis uses physicochemical data which are easy to obtain. These include refractive index, density, and molecular mass. Molecular mass can be determined by measuring the viscosity at different temperatures (e.g., ASTM D 2502). Carbon distribution is given in $\%C_A$, $\%C_N$ and $\%C_P$ (100 % in total). N – D – M analysis also determines the average total number of rings per molecule (R_T) and the breakdown into aromatic and naphthenic rings (R_N) per molecule ($R_N = R_T - R_A$).

Brandes [57] created a method of determining carbon distribution according to specific bands in the infrared spectrum (see Section 16.2.4). Exact determination of aromatic carbon content can be performed by NMR (ASTM 5292).

Hydrocarbon Composition. To determine the hydrocarbon composition of the base oil, the componenets are first separated by chromatography and the fractions are then subjected to advanced analytical procedures.

To differentiate mineral oils in the boiling range from 200 to 550 °C, high ionizing voltage mass spectrometry (ASTM D 2786-91) is used for saturated fractions and ASTM 3239-91 for aromatic fractions. Saturated fractions are separated into alkanes (0-ring), 1-ring, 2-ring, 3-ring, 4-ring and 5-ring naphthenes. The aromatic fractions are subdivided into seven classes: monaromatics, diaromatics, triaromatics, tetraaromatics, pentaaromatics, thiophenoaromatics, and unidentified aromatics.

Polycyclic Aromatics in Base Oils. Polycyclic aromatics (PAH, polycyclic aromatic hydrocarbons, or, in general, PCA, polycyclic aromatics) formed by the combustion of gasoline can accumulate in engine oils. They can also accumulate in quenching oils after long periods of heavy-duty use.

In traditional solvent refining processes, PAH largely remain in the extract. Nonsolvent extracted distillates contain PAH in line with their boiling point.

The carcinogenic characteristics of nonseverely treated distillates in the petroleum industry was established by the International Agency for Research on Cancer (IARC) in 1983 [58]. This led to considerable limitations in the manufacture and application of naphthenic base oils and the ending of the use of aromatic extracts as lube base oils.

PAH can be determined by HPLC with anthracenes or other aromatics as markers or by GC – MS after appropriate sample preparation.

The IP 346 method, adopted into national legislation in several countries, does not analyze PAH directly but an extract is obtained in dimethyl sulfoxide (DMSO), in which PAH accumulate. As a rule, the extract largely contains naphthenes or mono-aromatics. According to IP 346, DMSO extracts contain only 0.1 % PAH. After numerous skin-painting tests on mice, the carcinogenicity of petroleum products corresponds to the percentage of DMSO extract.

4.3. Refining (→ Oil Refining)

Lubricant refineries are divided into integrated and nonintegrated plants (Fig. 12). Integrated refineries are linked to primary crude oil refineries and are fed with vacuum distillate by pipeline. Nonintegrated refineries purchase vacuum distillate on the open market or buy atmospheric residues and perform their own vacuum distillation. Occasionally they perform vacuum distillation on crude oil.

4.3.1. Distillation

By way of fractional distillation, products are removed from crude oil which approximately meet the viscosity grades ultimately required. Often only four or five cuts suffice to fulfil lubricant requirements. The viscosity of the primary vacuum distillate is not identical to that of the finished base oils formed in hydrocracking processes.

After the corresponding separation of the lighter components from the crude oil by atmospheric distillation, the lubricant components are in the atmospheric residue. Figure 13 shows the yields of the various cuts in conventional lube oil refining with the corresponding boiling ranges of a typical lube crude. The atmospheric residue is now subjected to vacuum distillation to remove the components required for lubricants.

4.3.2. Deasphalting (→ Oil Refining, Chap. 3.6.5.1.)

The vacuum residue still contains highly viscous hydrocarbons which can supply valuable components for lube base oils. These highly viscous base oils, commonly known as brightstocks, are separated from the asphaltenes by extraction. Brightstocks are produced in lube oil refineries when the use of the asphaltene byproduct (hard asphalt) is worthwhile. The quality of the hard asphalt for the manufacture of high quality bitumen depends on the crude oil. Deasphalting is usually carried out with propane as solvent. Brightstocks can be manufactured with viscosities of more than 45 mm^2/s at 100 °C.

Figure 14 shows a flow sheet for the manufacture of suitable feeds for lube oil refining by distillation and propane deasphalting.

Figure 12. Integrated (1) and not integrated (2) lube refinery
A) Atmospheric distillation; B) Vacuum distillation; C), D) Processing of vacuum distillates for non-lube production
a) Fractionating vacuum distillation; b), c) Lube refining processes

4.3.3. Traditional Refining Processes

The vacuum distillates still contain components which can detrimentally affect aging, viscosity – temperature behavior and flowing characteristics, and components which are hazardous to health. To eliminate these compounds several refining methods were developed, of which solvent refining has become the most accepted method over the past few decades. New plants increasingly use hydrotreatment.

4.3.3.1. Acid Refining

Acid refining has become less popular because the acid sludge waste produced is difficult to dispose of and this method has been replaced by solvent extraction. Acid refining is still used to some extent for the re-refining of used lubricating oils (Chap. 18) and for the production of very light-colored technical or pharmaceutical white oils and petroleum sulfonates as byproducts.

When the distillates are treated with concentrated sulfuric acid or fuming sulfuric acid (oleum), substances which accelerate oil aging are removed. *Oleum treatment* (*wet refining*) not only readily removes reactive oil components such as olefins but also reduces the aromatic content, which in turn increases the viscosity index of the product. Reactions of oleum with saturated paraffinic structures lead to refining losses. Acid-refined oils require complex neutralization and absorption follow-up treatment to remove all traces of acid and undesirable byproducts.

4.3.3.2. Solvent Extraction

Solvent extraction (Fig. 15) creates base oils which are known as solvent raffinates or solvent neutrals (SN). Extraction processes using solvents create both a base oil and, after evaporation of the solvent, an aromatic-rich extract. The selectivity of the extraction media for aromatics is an important selection parameter.

Figure 13. Yield of the various cuts in conventional lube oil refining of a typical lube crude

Figure 14. Flow sheet for the manufacture of suitable feeds for lube oil refining by distillation and propane deasphalting

Figure 15. Solvent extraction

In particular the selectivity towards polycyclic aromatics has attracted attention because of the carcinogenicity of these compounds. Common extractants are furfural, *N*-methyl-2-pyrrolidone (NMP), and phenol. Sulfur dioxide should also be mentioned because of its historical importance as B. EDELEANU introduced extraction to petroleum technology in 1912. In 1999, sulfur dioxide was only used in very few refineries (one in Germany until 1999) for the refining of naphthenic distillates.

In recent years several furfural extraction plants have been converted into NMP plants, and even phenol plants have taken a back seat. NMP is a nontoxic solvent and can be used in a low solvent-to-oil ratio with high selectivity. This generates significant energy savings. NMP in new plants results in physically smaller units and thus lower capital expenditure.

Depending on the crude, the extract part of paraffinic oils can be 30 to 50 %. As the standard requirement of solvent neutral oils is a viscosity index of at least 95, the extraction severity is matched to this demand.

A higher proportion of aromatic and naphthenic hydrocarbons in the distillates requires greater extraction severity and thus a larger quantity of extract. The percentage share of the extract is a major economic factor in conventional lube refining. Aromatic extracts have a very high viscosity – pressure coefficient (Chap. 3) and in the past were often used in metal-forming operations, such as cold extrusion.

A 1-point increase in viscosity index as a result of greater extraction severity creates, on average, 1 % more extract. Some refineries produce so-called semiraffinates with *VI*s of between 70 and 80. It is cheaper to adjust the *VI* later with *VI* improvers than to produce 15 or 20 % more extract. These semiraffinates, however, have disadvantages resulting from the lower extraction severity – e.g., lower oxidation stability, possibly higher amounts of sulfur or higher amounts of polycyclic aromatics.

Solvent extraction is generally only economic to a minimum *VI* of 50 of the vacuum gas oil [59].

4.3.4. Solvent Dewaxing (→ Waxes, Chap. 4.2.3.1.)

In traditional refining processes, solvent extraction is followed by solvent dewaxing. Long-chain, high melting point paraffins (waxes) crystallize at low temperature and thus negatively affect the cold flow properties of lube oil distillates and lead to a high pour point. Their removal has, therefore, been an important consideration since the beginning of crude oil refining.

Dewaxing by crystallization of paraffins at low temperatures and separation by filtration are

the principal processes in traditional refining. Compared with catalytic dewaxing with hydrogen, urea dewaxing to separate *n*-paraffins is of relatively minor importance in lube oil refining. Crystallization methods involve mixing the solvent with the oil; this improves filtration, as a result of dilution, and promotes the growth of large crystal formations.

Solvents used for dewaxing are ketones and chlorinated hydrocarbons. *Ketone dewaxing* (dimethyl ketone or methyl ethyl ketone, MEK) is normally used for pour points down to −12 °C. For lower pour points, the *Di–Me* (dichloroethane – dichloromethane mixtures) method is used. This also enables the manufacture of hard and soft waxes. These waxes are only valuable products if their quality and processing is good and they can then be sold, e.g., as candle wax or for coatings. They are often used as cracker feed in fluid catalytic crackers (FCC) and the cracker yield is then assessed by use of special formulas.

Figure 16 illustrates the conventional solvent dewaxing process.

4.3.5. Finishing

A finishing stage often follows extraction and dewaxing. In the past, methods which employed absorbents were often used but these days predominantly hydrofinishing processes are used. Finishing should improve the color of the product and remove surface-active substances which can negatively affect the air-release or demulsifying properties of a lubricating oil.

In general, the hydrofinishing process is referred to as mild hydrotreating and focuses on improving color, odor, and ultraviolet stability. *Ferrofining* (BP) has achieved major economic importance as a finishing process. The process parameters do not generally lead to desulfurization. More severe processes with pressures in excess of 100 bar can bring about significant desulfurization and some dearomatization.

Additional finishing with absorbents (bleaching clays, bauxite) is sometimes used for the manufacture of refrigerator, transformer, or turbine oils. The subsequent filtration process in filter presses or other filtering equipment represents additional complexity and the disposal of the filter residue is an increasing problem.

Lube Crudes. The finished base oils have a high sulfur content, especially after conventional solvent refining. Hydrogenating processes almost fully eliminate sulfur but desulfurization consumes hydrogen.

The vacuum gase oils (VGO) are the direct feed for lube refining. Their *VI*, wax content, and sulfur content is especially important. A high *VI* leads to low extraction losses in solvent extraction and low hydrogen consumption during hydrogenation. High wax content increases production costs.

Table 2 shows the *VI* and wax content of VGO from various lube crudes.

Table 2. *VI* and wax content of vacuum gas oil (VGO) from various crudes

Crude	*VI* after solvent dewaxing	Wax in VGO (wt %)

4.4. Base Oil Manufacturing by Hydrogenation and Hydrocracking

(→ Oil Refining, Chap. 3.3., → Oil Refining, Chap. 3.5.)

Hydrogenation and hydrocracking in the manufacture of lubricant base oils significantly influence the chemical structures of mineral oil molecules. Unstable molecules are chemically stabilized by the removal of the heteroatoms (sulfur, oxygen, nitrogen) and severe hydrogenation can convert aromatics into saturated naphthenic or paraffinic structures. In addition to the hydrogenation process, hydrocracking breaks down or cracks larger molecules into smaller ones. Larger molecular structures can re-form from small fragments. The principal process criteria are temperature, pressure, the catalyst and space velocity. If special conditions are met, a focal point of the process is the isomerization of paraffinic structures. Beside the saturation of

Figure 16. Conventional solvent dewaxing process

aromatics, opening of the naphthenes rings can occur.

Lubricant base oils can be much more easily tailored using these processes than is possible with simple solvent refining separation. The future of lube base oil production thus lies with hydrogenation and hydrocracking. An additional advantage of advanced hydrocracking is the lower dependence on the quality of the crude oil.

In addition to hydrocracking and hydroisomerization, the following typical chemical processes occur during hydrogenation (Table 3).

While the processes mentioned are generally replacing solvent extraction for the manufacture of base oils, there are hydrogenation processes which either crack long-chain paraffins with specific catalysts into light products and remove them from the base oil or convert them into isoparaffins with good low-temperature characteristics without a significant loss in yield. If the previously mentioned hydrogenation processes are combined with this type of catalytic hydrogenating dewaxing, this is called the 'all-hydrogen route'.

4.4.1. Manufacturing Naphthenic Base Oils by Hydrogenation

Only about 10 % of the petroleum base oils used in lubricants are naphthenic. Before 1980, naphthenic oils were significantly more important (USA 25 %). In 1983, a publication by the IARC defined a number of mineral oil products as carcinogenic, among them naphthenic oils. Although the IARC publication and subsequent legislation and classification requirements led to the disappearance of this type of oil from important markets, naphthenic base oils were still required for some lubricant applications (greases, metalworking oils, and refrigerator oils) because of their outstanding solubility and these are now manufactured with severe hydrogenation which produces noncarcinogenic base oils. Figure 17 shows a flowchart for the manufacture of naphthenic base oils. Severely hydrotreated Group C distillates are the most accepted naphthenic base oils in western markets.

4.4.2. Production of White Oils

White oils – light-colored, odorless, low-aromatic or aromatic-free mineral oil raffinates – are used in a number of applications as medical and pharmaceutical white oils or technical white oils in, above all, the food and beverage industries as food-grade lubricants. BASF Germany was the first to develop white oil manufacturing from the high-pressure hydrogenation technology used to liquefy coal. Up to that point, white oils were manufactured exclusively by acid treatment.

Table 3. Typical chemical processes during hydrogenation

Desulfurization	Mercaptans $R-SH \rightarrow RH + H_2S$ Disulfides $R-S-S-R \rightarrow RH + H_2S$ Sulfides $R-S-R \rightarrow RH + H_2S$ Thiophene Denitrogenation	Polyaromatic saturation Viscosity Index: (a) −60; (b) 20 Pour point: (a) +50 °C; (b) +20 °C	 Naphthenic ring opening Viscosity Index: (a) 20; (b) ∼130 Pour point: (a) +20 °C ; (b) −10 °C	Isomerization Viscosity Index:(a) 125; (b) 125 Pour point: (a) +20 °C; (b) −40 °C	

Figure 17. Manufacture of naphthenic base oils

The feeds for hydrogenated white oil manufacturing are generally naphthenic or paraffinic solvent-treated vacuum distillates or untreated vacuum distillates. In the BASF process hydrogenation takes place in two stages: the first at 300 – 380 °C and 80 – 200 bar with a NiMo catalyst and the second at 200 – 300 °C and 100 – 200 bar with an Ni catalyst. The first stage produces the technical qualities (according to the U.S. Food and Drug Administration) while the second stage produces the medical grades (e.g., German Pharmacopeia). Figure 18 shows a flow chart for white oil manufacture [59].

4.4.3. Lube Hydrocracking

The principal elements of the lube hydrocracking process are the cracking of low-*VI* components and the saturation of aromatics.

Hydrocracking can be performed with the principal objective of producing lubricating oils and to convert vacuum gas oil into high-grade fuels. Fuel hydrocracker residues are excellent feeds for the manufacture of lubricant base oils and hydrocrackers used to make olefin feeds for steam crackers can supply a premium quality feed for lube base oils. The severity has the most important effect on the quality of the base oil produced. High severity (e.g., 80 % light products) generates a high-*VI* and low-evaporation oil. While hydrocracking refineries for base oils with normal *VI*s and normal Noack evaporation (high viscosity index, HVI oils, Group II oils, Section 16.1) at moderate severity are being built in the USA and the Far East, based mainly on Chevron Technology, Western European hydrocracking plants were designed for low-evaporation base oils (Shell, Petit Couronne, France, 1972; Union Fuchs, Wesseling, Germany, 1986 and BP, Lavera, France). These produce Group III oils, both from waxes and from vacuum gas oils with hydrocracker residues.

Hydrocracked base oils differ from solvent-extracted oils by their extremely low aromatic content and their chemical purity, i.e., only traces of heteroatoms such as sulfur, nitrogen, or oxygen are present. Furthermore, Group III oils which were manufactured at high severity or from waxes have Noack evaporation characteristics which are about 50 % lower than equiviscous, solvent-extracted vacuum distillates. If catalytic dewaxing is performed, even lower pour points can be achieved than with SN oils.

Since 1995, more than half of all new base oil manufacturing plants have been built or are planned using hydrocracking technology.

The increasing number of fuel hydrocrackers, which are a response to increasing demands for low-sulfur oils (diesel fuels with < 50 ppm sulfur), represents a growing source of hydrocracked feeds. Fuel hydrocracker residue can be processed into high-quality, hydrocracked base oils by distillation and subsequent dewaxing (wax isomerization) at acceptable cost.

During the hydrocracking process, especially if vacuum gas oils are severely treated to create very high viscosity index (VHVI) oils, polycyclic aromatics can be formed along with saturated structures (aromatics to naphthenes or paraffins and isoparaffins) under some process conditions. These have to be removed by subsequent high-pressure hydrogenation or by extraction if hybrid methods are used. This subsequent hydrogenation can also be manipulated so that it also produces a significant increase in *VI*.

4.4.4. Catalytic Dewaxing

The most complex stage of traditional base oil refining is solvent dewaxing. In addition to the high capital expenditure and, above all, operating cost, the solvent-related limits to the achievable pour point are a disadvantage.

Thus, various methods have been developed which can remove unbranched and less branched paraffins, and some other petroleum components by catalytic and hydrogenation reactions or convert them into components which improve the low-temperature characteristics of the base oil.

The first technologies were based on the catalytic cracking. In 1979, Mobil introduced the *Mobil lube dewaxing process* (MLDW). The development of catalysts since then has led to strong hydroisomerization activity processes (*Mobil selective dewaxing*, MSDW).

While the MLDW process mainly involves the cracking of long-chain paraffins and the production of larger quantities of light byproducts and poor base oil yields, MSDW processes create high-yield, nonwaxy isoparaffins from the waxy parts of the feed.

Figure 18. Flow chart for white oil manufacture (BASF)

At the beginning of the 1990s, Chevron successfully introduced its *isodewaxing* process. In 1999 it was the most important technology for catalytic dewaxing [59]. The process combines relatively high yields with low pour points and high *VI*s. The method uses an intermediate-pore silicoaluminumphosphate molecular sieve (e.g., Pt on SAPO-11) as catalyst. In terms of process economy, high base oil yields but also theformation of mainly high-value C_{5+} liquids as by-products are of significance.

Dewaxing catalysts must possess the right balance between hydrogenation activity and acid activity. Increasing hydrogenating properties usually leads to a reduction in paraffin isomerization and thus a rise of the pour point. Higher acid activity increases cracking and thus yield losses. Sulfur and nitrogen in the feed play important roles. Nitrogen is detrimental to acid activity and sulfur is catalyst poison.

Isodewaxing in principle enables manufacture of lubricant base oils with pour points below $-45\,^{\circ}C$, however, dewaxing to very low pour points (depending on process conditions and catalysts) leads to *VI* losses.

A major success of this new dewaxing process are the molecular sieve catalysts – zeolites with exactly defined mesh sizes. Although highly branched paraffins or polycyclic naphthenes or aromatics are not affected by the zeolites, long-chain less or unbranched molecules are isomerized by the catalysts [60–62].

Figure 19 shows the flow chart for catalytic dewaxing (hydrodewaxing) including a hydrofinishing reactor.

4.4.5. Wax Isomerization

VHVI oils have been manufactured from wax cuts from solvent extraction processes since the early 1970s. The conversion of long-chain normal paraffins or less branched paraffinic components into isomerized products with good low-temperature characteristics and high *VI*s succeeded, with suitable catalysts, in isomerizing hydrocracking processes. Because the input feed is already aromatic- and naphthene-free, the catalysts can be fully optimized to the conversion of the paraffinic material. At relatively high yield losses, the process creates high-quality but comparatively expensive hydrocracked oils (Shell XHVI, Exxon Exxyn, Mobil MWI-2 catalyst).

4.4.6. Hybrid Lube Oil Processing

The combination of traditional solvent refining with severe hydrotreating and hydrocracking processes is known as hybrid processing. To create higher *VI*s (> 105) and to reduce sulfur content, hydrotreating can follow solvent extraction (e.g., in the manufacture of turbine oils).

The combination of a mild furfural extraction with hydrocracking can produce hydrocracked oils by low-hydrocracking conversion in small reactors. The low hydrogen consumption adds to the economy of such processes. The introduction of a hydrocracking stage into a conventional solvent refinery offers the attractive possibilities of de-bottlenecking if the corresponding dewaxing capacity is available.

Catalytic dewaxing can, on the other hand, follow solvent refining. This presupposes that

Figure 19. Flow chart for catalytic dewaxing (hydrodewaxing) including hydrofinishing

the catalytic dewaxing catalysts are not poisoned by the sulfur and nitrogen components in the solvent raffinate. In the Mobil processes, this is more likely with MLDW catalysts than with MSDW catalysts.

Several other high-paraffin components should be considered as future base oil feeds. These could include high-wax (> 70 %) natural distillates and Fischer – Tropsch waxes or synthetic fluids from natural gas.

The quality of low-quality lube feeds (VGO) can be improved by hydrogenation before solvent extraction (Hy-starting or Hystart).

4.4.7. All-Hydrogen Route

The production of base oils by hydrocracking and catalytic, solvent-free dewaxing is called the all-hydrogen route. Figure 20 shows a flow sheet for such a refinery used to manufacture VHVI oils. Depending on the severity of the hydrocracker, Group II HVI or Group III VHVI oils can be produced (HC-I and HC-II oils, Table 4). Leading examples for HC-I oils are the Chevron refinery in Richmond, California and the Conoco – Pennzoil refinery in Lake Charles (Exel Paralubes) [63]. Some HC-I refineries have been prepared to produce HC-II oils by the all-hydrogen route by increasing the severity of the hydrocracker. Another example of a hydrocracker refinery is the Petro-Canadas plant [64].

The use of a fuel hydrocracker for the production of base oils using the all-hydrogen route was first realized by the SK Corporation (Ulsan, Korea) in 1995. By recycling the hydrocracker bottom and the special integration of the fuel hydrocracker in the lube oil process, SK also developed a specific method (UCO process, Fig. 21) [65].

4.4.8. Gas-to-Liquids Conversion Technology

As a result of efforts to increase the value of natural gas in logistically favorable locations, the chemical liquefaction of natural gas (also the chemical reaction route) was developed (on the basis of the Fischer – Tropsch process; → Waxes, Chap. 5.). This process creates high-quality liquid products and paraffin wax. High-quality UHVI oils can then be obtained from natural gas by part oxidation, polymerization, and isomerization [66], [67].

The base oil market could undergo dramatic changes if Fischer – Tropsch waxes, which are part of gas-to-liquids technology, become more generally available. Shell has used such waxes from its Bintulu plant in Malaysia for its XHVI's. New technologies for smaller, efficient plants have been developed by Entech and Syntroleum in the last years.

4.5. Boiling and Evaporation Behavior of Base Oils

The target of base oil distillation is the viscosity desired at 40 °C and 100 °C. The same distillation cut (same boiling point distribution) with different chemical structures leads to different viscosities. A highly naphthenic cut produces a higher viscosity than a paraffinic cut. In other words, equiviscous cuts of different chemical structures have different boiling-point distributions.

Figure 22. Distillation curves of three paraffinic solvent refined cuts
A) Light cut (low boiling); B) Medium light cut; C) Heavy cut (high boiling); D) Blend of A and C, equiviscous with B

In practice, ISO viscosity grades or other required viscosities are created by blending different cuts. If the boiling points of both cuts are too far apart, the flash point drops significantly and evaporation increases. Figure 22 shows the distillation curves of three paraffinic solvent refined cuts. One line is a blend of cut A with cut C which creates an equiviscous oil with cut B. The share with a boiling range up to 380 °C increases from 10 % (equiviscous cut) to 20 % (equiviscous blend).

Apart from the use of a variety of laboratory distillation apparatus to determine the boiling point distribution of a base oil, gas chromatographic methods of determining boiling point have gained popularity over the last few years. Both nonpolar packed and capillary gas chromatographic columns can be used. The injection port temperature is between 360 and 390 °C depending on the length of the column. The initial column temperature can be as low as − 50 °C, the final column temperature is between 360 and 390 °C and the programming rate is usually below 10 °C/min.

In recent years, the evaporation characteristics of lubricants have become increasingly important quality criteria. The reasons for this are the emissions created when a lubricant evaporates, and the accompanying change to the lubricant's composition. The topic of evaporation behavior has become increasingly important in line with the trend towards lower viscosity oils for most applications (energy-saving oils).

As a simple laboratory method, *Noack evaporation* (1 h at 250 °C) has become the established method of characterizing evaporation behavior in lubricant specifications with the evaporation losses being given in wt %. Gas chromatographic methods are also used but these can produce somewhat deviating results.

This led to a simulated Noack evaporation method using gas chromatography. In the USA, a gas chromatographic process was developed to determine engine oil volatility (ASTM D5480). In this case, evaporation takes place at 371 °C (700 °F) and the evaporating components are measured to ca. n-C_{22}. Although this process is easily reproducible, the values obtained are not comparable with those from the Noack method.

Figure 23 shows typical evaporation losses for well-cut paraffinic solvates; values for VHVI oils (HC-II oils, API Group III oils and typical ester base oils (Chap. 5) are shown for comparison.

Figure 23. Typical evaporation losses (Noack evaporation) of various lube base oils (250 °C, 1 h)

5. Synthetic Base Oils

Classes of synthetic lubricants according to GUNDERSON and HART [68] and SHUBKIN et al. [69] are listed in Table 5.

Table 5. Classes of synthetic lubricant

GUNDERSON and HART (1962) [68]	SHUBKIN et al (1993) [69]
	Alkylated aromatics
Chlorofluorocarbon polymers	Chlorotrifluoroethylene
	Cycloaliphatics
	Dialkylcarbonates
Dibasic acid esters	Esters
Fluoro esters	
Neopentyl polyol esters	
	Perfluoroalkylpolyethers
Phosphate esters	Phosphate esters
	Phosphazenes
	Polyalphaolefins
	Polybutenes
Polyalkylene glycols	Polyalkylene glycols
Polyphenyl ethers	
	Silahydrocarbons
Silicate esters	
Siloxanes	Siloxanes

Although many of the synthetic base oils available today had been developed decades ago, their use on a large technical scale has increased only slowly because of their considerably higher cost [70], [71] (Table 6).

Table 6. Relative costs of synthetic base oils (relative to 1 for mineral oils in 1999)

Type	Relative cost
Alkylated aromatics	2–3
Polybutenes	3–5
Dibasic acid esters	7–15
Polyalkylene glycols	7–20
Polyalphaolefins	7–25
Neopentyl polyol esters	10–20
Siloxanes	40–200
Perfluoroalkylpolyethers	400–800

However, the consumption of polyalphaolefins, the most common synthetic lubricating oils, has increased enormously since the 1980s [72–74].

Synthetic base oils usually are prepared by reaction of a few defined chemical compounds – in many cases based on petroleum also – and tailored to their application by the right choice of reaction conditions.

Synthetic base oils have been classified according to both the production process and their chemical composition [71], [75]. From a chemical point of view the latter method is preferable.

5.1. Synthetic Hydrocarbons

Synthetic hydrocarbons were developed simultaneously in Germany and the United States. In Germany low-temperature performance and the

need to overcome the general shortage of petroleum base stocks was the driving force [76]. All synthetic hydrocarbons – and the other economically important synthetic lubricating oils – can be synthesized starting with ethylene.

5.1.1. Polyalphaolefins

The term polyalphaolefin (PAO) is derived from the source of this class of base oil, usually α-decene or a mixture of α-olefins containing, in general, a minimum of six and a maximum of twelve carbon atoms. Linear α-olefins were first used for the synthesis of lubricating oil by MONTGOMERY, GILBERT, and KLINE [77]. Polyalphaolefins have been described in detail in [74].

Oligomerization of α-olefins is generally carried out by boron trifluoride-based Friedel – Crafts oligomerization with alcohols as co-catalysts. Possible mechanisms have been described in detail in [78]. The boron trifluoride method has become predominant for the production of grades with lower viscosities, 2 – 10 mm^2/s. For higher viscosities, 40 and 100 mm^2/s, other catalysts must be used, and for the production of grades with viscosities of 10 – 25 mm^2/s, C-12 and C-14 olefins can be used; these yield mainly dimers [79]. In the next step the unsaturated olefins obtained are hydrogenated, using, e.g., nickel on kieselguhr or palladium on alumina as catalysts. In a third and final step the saturated oligomers are distilled. The oligomerization of α-decene or α-olefin mixtures always results in complex mixtures of isomers with more branching than expected. Because the rearrangements are intramolecular, the molecular masses of the products can be kept within a narrow range. A typical saturated α-decene trimer for example looks like a three-pointed star [80] (Fig. 24).

Polyalphaolefins therefore have several advantages – narrow boiling ranges, very low pour points, $VI > 135$ for all grades with kinematic viscosity $> 4\,mm^2/s$ at 100 °C. Their volatility is lower than that of all possible and equiviscous mineral oil grades and they contain only small quantities of unsaturated and polycyclic aromatic compounds and only traces of nitrogen, sulfur, or other impurities. Although in some oxidation tests without additives some mineral oils seem superior to polyalphaolefins, this is because of the presence of natural antioxidants in the mineral oils that have survived the refining process. The response of the synthetic products to antioxidants and their extreme pressure/antiwear synergists is better [81–83] than that of mineral oils. Their low polarity, on the other hand, leads to poorer solvency for very polar additives and can cause problems with seals. Therefore, PAOs tend to be used in combination with smaller amounts of (dicarboxylic acid) esters or solvent-refined mineral oils.

Polyalphaolefins have been used traditionally in aerospace and lifetime applications, but today they are used in a wider variety of applications and have gained additional importance because of the increasing need for them in automotive lubricants [84].

5.1.2. Polyinternalolefins

Polyinternalolefins (PIO) are rather similar to polyalphaolefins. Both kinds of hydrocarbon are prepared by the oligomerization of linear olefins. The difference is that polyinternalolefins are made from cracked paraffinic base stocks. Plants for the manufacture of polyinternalolefins and polyalphaolefins therefore look similar (Fig. 25). Internal olefins are more difficult to oligomerize and the resulting products have *VI*s 10 to 20 units lower than the *VI*s of equiviscous polyalphaolefins [85].

Mixtures of polyalphaolefins with polyethylenes with kinematic viscosities from 100 to 2000 mm^2/s at 100 °C are available commercially.

While the cationic polymerization of ethylene with aluminium chloride yields oils with *VI*s up to 120 and molecular masses from 400 to 2000, the polymerization of propylene gives oils with lower *VI*s and poor thermal stability. Both kinds of lubricating oil have lost importance, but copolymers of both base materials are said to have the potential for gaining importance again.

5.1.3. Polybutenes (→ Polyolefins, Chap. 4.)

Polybutenes (PBs) as synthetic base oils have been described in detail in [86]. They consist

Figure 24. Molecular structures of typical polyalphaolefin oligomers

Figure 25. Schematic of a polyinternalolefin (polyalphaolefin) plant

mainly of isobutene and are, therefore, often also known as polyisobutenes (PIBs).

Polybutenes are produced by Lewis-acid catalyzed polymerization of the raw C_4 stream that beside isobutene contains the other two butenes and the butanes (→ Butenes). The process yields a copolymer with a backbone built mainly from isobutene units. The higher the molecular mass, the lower the content of other butenes, that is, the lower the molecular mass the more complex the structure. Polybutenes contain one double bond at the end of the carbon chain. Therefore, polybutenes are less resistant to oxidation than polyalphaolefins, polyinternalolefins, and alkylated aromatics – above 200 °C they begin to depolymerize and form gaseous products.

Polybutenes with molecular masses from about 300 to 6000 are important as *VI* improvers. They are used as components in two-stroke oils, gear and hydraulic oils, metal working lubricants, greases, compressor lubricants, and wire-rope protectives [87]. One of the options for future polybutene applications is the increased use as synergistic components in binary or ternary base oil systems [88].

5.1.4. Alkylated Aromatics

Alkylnaphthalenes as lubricants have been available in Germany since ca. 1930 [89], [90]. Low-cost dialkylbenzenes are produced as by-products in the manufacture of linear and branched monoalkylbenzenes that themselves are feedstocks for the manufacture of detergents. The Friedel – Crafts alkylation of benzene with olefins tends to yield polyalkylated products, because of the reactivity of the primary product. With excess benzene, a suitable olefin, e.g., propene, and the right choice of a catalyst the reaction can be controlled and specialized alkylbenzenes can be synthesized.

Lower-cost dialkylbenzenes are used in a wide variety of industrial areas, e.g., in transformer oils, where high resistance to gas evolution is important. Tailored grades, especially the linear products, although having poorer properties than polyalphaolefins, still are an option because of their excellent solvency, their suitability for low temperatures, and their compatibility with elastomers [91]. The most widespread use of these products is, however as refrigerator oils.

5.1.5. Other Hydrocarbons

Cyclic saturated or alicyclic hydrocarbons (naphthenes) occur naturally as components of mineral oils. Naphthenes do not yet have comparable synthetic analogs available on a technical scale.

5.2. Halogenated Hydrocarbons

Chlorinated hydrocarbons are very stable and not combustible. They were once widely used as insulating oils, heat-transfer fluids, and hydraulic fluids, but this use has been discontinued because of the environmental problems they cause.

Commercial liquid chlorofluorocarbons, all oligomers of chlorotrifluoroethylene (→ Fluorine Compounds, Organic, Chap. 4.7.), contain between two and twelve monomer units. They are suitable for use as lubricants mainly because of their extraordinary chemical stability, including against oxygen.

Their low corrosivity, the good low-temperature characteristics of the low-viscosity grades, and their lubricating properties are also advantageous. Disadvantages are their high volatility and their not ideal $V-T$ dependence. Their density naturally is relatively high (between 1.7 and 2 g/mL at 40 °C). Chlorofluorocarbons are used as lubricants in oxygen compressors, in pumps for mineral acids, halogens, and oxygen, and in mills or mixers for strong oxidizing agents. They are also suitable lubricants for turbine pumps in rocket engines and as base oils for non-flammable hydraulic fluids [92].

5.3. Synthetic Esters

5.3.1. Esters of Carboxylic Acids (→ Esters, Organic)

Synthetic ester lubricants for jet engines were developed in Germany during World War II [93].

Carboxylic groups, because of their strong dipole moments, reduce the volatility and increase the flash point of lubricating oils, and at the same time positively affect thermal stability, (the bonds of the COO group are thermally more stable than the C – C bond), solvency, lubricity, and biodegradability. On the other hand, however, they negatively affect the hydrolytic stability of a lubricant and the reactivity with metals or alloys that contain copper or lead [94].

5.3.1.1. Dicarboxylic Acid Esters [95]

Two types of ester molecule or their combinations have been found to be most suited as lubricant components:

1) Esters of branched primary alcohols with straight-chain dicarboxylic acids, and

Di(2-ethylhexyl)adipate

2) Esters of straight-chain primary alcohols with branched dicarboxylic acids

Diundecyl(2,2,4-trimethyl)adipate

The alcohols that are needed for the production of dicarboxylic acid ester oils can be obtained synthetically by the hydroformylation of olefins with carbon monoxide and hydrogen (→ Oxo Synthesis). The dicarboxylic acids can be obtained either by oxidation of vegetable oils, e.g., castor oil, as for azelaic and sebacic acid [96], or by cleavage of corresponding alicyclic hydrocarbons with oxygen, as for adipic acid [97].

Esters of straight-chain dicarboxylic acids have better $V-T$ characteristics than mineral oils, and higher VI values. The values decrease with increasing branching, but branching improves the low-temperature properties. Esters with little branching have the best properties, especially esters with methyl groups adjacent to the carboxyl group.

Dicarboxylic acid ester oils can improve the $V-T$ characteristics of automotive engine oils without having a negative effect on the low-temperature viscosity or the Newtonian flow behavior. Such oils are suitable for diesel engines also. Esters have also gained importance as lubricity additives in greases and in polyalphaolefins as additives for the improvement of the compatibility with elastomers.

5.3.1.2. Polyol Esters

Since the 1940s neopentyl glycol ((2,2-dimethyl)-1,3-propandiol), trimethylolethane and -propane (1,1,1-tris(hydroxymethyl)ethane and -propane), and pentaerythritol (2,2-bis(hydroxymethyl)-1,3-propanediol) have been used as the alcoholic components of esters [98]. Beside excellent thermal and oxidation stability, the esters have good $V-T$ and lubricating properties and excellent viscosity characteristics at low temperatures.

The mechanism of the polymerization of polyol esters during aging has been studied [99] and benzotriazole derivatives have been proposed as multifunctional additives [100]. Since the 1960s the polyol esters have gained importance as lubricants for high-temperature applications, for example in aircraft engines that are meant for speeds beyond Mach 2, and they have become even more important as biodegradable esters.

5.3.1.3. Other Carboxylic Esters

Esters of some aromatic polycarboxylic acids (**1**), mainly phthalic acid (**2**), trimellitic acid, and pyromellitic acid (**3**), with monofunctional alcohols are also used as base oils. The latter are suited as high temperature lubricants. The time dependence of the low-temperature viscosity of some grades is rather pronounced. Therefore their use in low temperature applications is problematic.

1

2

3

Monoesters of fatty acids and monofunctional alcohols are used in metal working. The sulfurized esters are excellent extreme pressure additives for all kinds of lubricant [101].

Dimeric acid esters, formed by dimerization of esters of oleic or tallow fatty acid, are used as engine oil and thickener components.

5.3.1.4. Complex Esters

Esters that contain straight or branched diols or polyalkylene glycols and straight or branched dicarboxylic acids as well as (mono)carboxylic acids and monofunctional alcohols have attracted interest. Usually first the diol is esterified with the dicarboxylic acid, then, depending on the desired product, the intermediate product is reacted with either a carboxylic acid or a monoalcohol. Two types of complex ester have become important:

A)

ROH · · · HOOCrCOOH · · · HORrROH
· · · HOOCrCOOH · · · HOR

B)

RCOOH · · · HORrROH · · · HOOCrCOOH
· · · HORrROH · · · HOOCR

The same scheme is valid when neopentane derived polyols [102] or glycerol [103] are involved.

Complex esters have higher molecular masses and higher viscosities than the common esters. Esters of type B are superior to type A with regard to flash point, pour point, and low-temperature viscosity. In type A polyalkylene glycols lead to lower pour points than aliphatic glycols.

High molecular mass complex esters of the type:

$$R \cdots (HOrOH \cdots HOOCrCOOH)_n \cdots R$$

have also been named polymer esters and find use mainly in applications where mineral oil and solvent resistance is required.

5.3.1.5. Fluorinated Carboxylic Acid Esters

Esters of fluorinated acids are readily hydrolyzed and the free acids have a strong oxidizing effect, therefore, only esters of nonfluorinated carboxylic acids with fluorinated alcohols can be used as lubricants. The thermal stability and the oxidation stability of fluorinated esters is better than that of the nonfluorinated analogs. Some types of rubber shrink in their presence and some antioxidants have a negative effect on their stability. Fluorinated esters were in the first place intended for high-temperature applications [104]. It can be assumed that their use will be limited because of competition from the fluorinated polyethers.

5.3.2. Phosphate Esters (→ Phosphorus Compounds, Organic, Chap. 10.) [105], [106]

Tertiary esters of phosphoric acid with alcohols or phenols were first prepared 150 years ago but were not introduced as antiwear additives before 1930. They have also gained importance as plasticizers, fire-resistant hydraulic fluids, compressor oils, and synthetic lubricants. They are usually divided into triaryl, trialkyl, and alkylaryl phosphates and are made by reaction of phosphoryl chloride with phenols or alcohols. Their properties range from low-viscosity fluids

to high-melting solids. With increasing molecular mass trialkyl phosphates change from water-soluble to insoluble liquids. The triaryl phosphates have higher viscosities and are insoluble in water. An aryl side-chain reduces the melting point. The properties of alkylaryl phosphates are between those of alkyl and aryl phosphates.

$$3\,ROH + POCl_3 \rightarrow OP(OR)_3 + 3\,HCl$$

The hydrolytic stability varies between good and poor. Alkylaryl phosphates are more susceptible to hydrolysis than trialkyl or triaryl phosphates. Phosphoric acid esters are less stable than carboxylic acid esters, but more stable than silicic or boric acid esters.

The thermal stability of triaryl phosphates is better than that of the alkyl compounds. With aminic antioxidants and rust inhibitors, triaryl phosphates can be used up to 175 °C, but alkyldiaryl phosphates only up to 120 °C. Branching of the alkyl radicals reduces the thermal stability, the effect becomes stronger with decreasing length. In general phosphoric acid esters are not corrosive. The high spontaneous ignition temperatures of up to 600 °C underline the good fire resistance of some products. Trialkyl and alkylaryl products have pour points down to − 65 °C, when they contain *VI* improvers.

The lubricating properties of the phosphates are excellent, particularly on steel. They can be blended with almost all lubricants and additives. Their dissolving power is, on the other hand, responsible for their incompatibility with rubbers, varnishes, and plastics. Nylon, epoxy and phenol – formaldehyde resins are stable.

5.4. Polyalkylene Glycols

(→ Polyoxyalkylenes) [108–110]

The first polyalkylene glycols suitable as lubricants were developed during World War II. The first patent was probably published in 1947 by Roberts and Fife [107].

Polyalkylene glycols are prepared by the reaction of epoxides, usually ethylene and propylene oxide, with compounds that contain active hydrogen, usually alcohols or water, in the presence of a basic catalyst, e.g., sodium or potassium hydroxide. Polymers with statistically distributed alkylene groups are made by use of a mixture of alkylene oxides. Separate addition leads to block copolymers. Because ethylene oxide is more reactive than propylene oxide, random copolymers tend to have the propylene oxide units at the chain ends.

Terpolymers with, for example, tetrahydrofuran have also been prepared. Pure tetrahydrofuran polymers can be obtained by polymerization of tetrahydrofuran in the presence of Friedel – Crafts catalysts. They are colorless oily or waxy substances of very low toxicity.

The miscibility of polyoxyalkylenes with water increases with the number of ethylene oxide units. In solution the water-soluble grades are practically nonflammable. The solubility in water decreases with increasing molecular mass and number of ether bonds. Solubility in hydrocarbons increases with the molecular mass. Polyalkylene glycols in general are soluble in aromatic hydrocarbons.

The molecular mass and viscosity of polyalkylene glycols can be significantly influenced during production and be adjusted within narrow limits. The possibility of engineering products in this way distinguishes them from many other lubricants.

Low-molecular-mass polyalkylene glycols containing more than 50 % propylene oxide have pour points that go down to − 65 °C. The lateral methyl groups are responsible for the disruption of crystallization. On the other hand pure high-molecular-mass polyethylene glycols are wax-like solids with pour points near + 4 °C.

Kinematic viscosities range from 8 to 100 000 mm^2/s at 40 °C. The *VI* values of polyalkylene glycols usually lie around 200. High-molecular-mass polyethylene glycols have *VI* values of up to 400.

Prolonged heating of polyalkylene glycols to above 150 °C leads to depolymerization. Traces of alkali or alkaline-earth metals promote the degradation. The decomposition can be prevented by addition of aminic antioxidants, to the extent that the oils can be used as heat-transfer fluids up to 250 °C.

The polar nature of polyalkylene glycols gives the products strong affinity for metals, and so the lubricating film remains intact even at high surface pressure, a property useful in lubricants and metal cutting fluids. Because swelling of elastomers decreases with increasing viscosity, polyalkylene glycols can be used with natu-

ral and with synthetic rubbers in hydraulic oils and brake fluids. Because of their low toxicity polyalkylene glycols find application in the food, pharmaceutical, tobacco, and cosmetics industries. Products with high ethylene oxide content are up to 80 % biodegradable. High viscosity water-soluble products are shear-stable liquid thickeners. Hydrophilic and hydrophobic fractions in block copolymers give them surfactant properties.

5.5. Other Polyethers

Alkylated aryl ethers, like alkyl ethers, have lower viscosities, lower *VI* values, lower pour points, and lower boiling points than the corresponding alkanes. Asymmetric substitution also reduces the pour point, but has an adverse effect on the $V-T$ relationship. Although such products have low viscosities, some have found use as components of lubricants used in the life sciences.

5.5.1. Perfluorinated Polyethers (→ Fluorine Compounds, Organic, Chap. 6.1.) [111–113]

Photochemical polymerization of tetrafluoroethylene in the presence of oxygen, followed by fluorination with elemental fluorine leads to products of type A (Eq. 5.1) in the case of tetrafluoroethylene. With hexafluoropropylene products of type B (Eq. 5.2) result. Anionic polymerization of hexafluoropropylene epoxide leads to products of type C (Eq. 5.3), and Lewis acid-catalyzed polymerization of 2,2,3,3-tetrafluorooxetane leads to products of type D (Eq. 5.4).

$$F_2C{=}CF_2 \xrightarrow{O_2/F} F_3C{-}O{-}\left[\overset{CF_3}{\overset{|}{CF}}{-}CF_2{-}O\right]_m{-}\left[CF_2{-}O\right]_n{-}CF_3 \quad (5.1)$$

$$F_2C{=}CF{-}CF_3 \xrightarrow{O_2/F} F_3C{-}O{-}\left[CF_3{-}CF_2{-}O\right]_m{-}\left[CF_2{-}O\right]_n{-}CF_3 \quad (5.2)$$

$$F_2\overset{O}{C}{-}CF{-}CF_3 \xrightarrow[(CsF)]{F} F_3C{-}CF_2{-}CF_2{-}O{-}\left[\overset{CF_3}{\overset{|}{CF}}{-}CF_2{-}O\right]_n{-}CF_2{-}CF_3 \quad (5.3)$$

$$H_2\overset{O-CF_2}{\overset{|}{C}}{-}\overset{|}{CF_2} \xrightarrow[(BF_3)]{F} F_3C{-}CF_2{-}CF_2{-}O{-}\left[CF_2{-}CF_2{-}CF_2{-}O\right]_n{-}CF_2{-}CF_3 \quad (5.4)$$

The density of the perfluorinated polyethers (PFPEs) is nearly twice that of hydrocarbons. They are immiscible with most of the other base oils and non-flammable under nearly all practical conditions. The more common types A and B have a good to very good $V-T$ and $V-p$ dependence, and low pour points [114]. The viscosity of linear PFPEs changes less with temperature and pressure than that of the non-linear variety; in air they are stable up to 400 °C. PFPEs are remarkably inert chemically and have an excellent hydrolytic stability.

The shear stability of PFPEs is better than that of other polymeric lubricants, but in the presence of steel and under boundary lubrication conditions PFPEs do not perform very well [115].

Perfluoropolyalkyl ethers have all the properties required by modern spacecraft: as lubricants and hydraulic fluids they resist to thermal and oxidative attack above 260 °C, possess good low-temperature flow characteristics, and are fire-resistant. They can also be used as power transmission and inert fluids and in transformers and generators as dielectrics with outstanding properties.

5.5.2. Polyphenyl Ethers

Polyphenyl ethers are formed by reaction of phenols and aryl halides [116]. Abbreviated formulas are in use. They contain the substitution position and the number of phenyl rings (ϕ) and ether bonds, for instance ppp5P4E stands for $\phi-O-\phi-O-\phi-O-\phi-O-\phi$ (p–p–p).

(5.5)

The aromatic groups increase the stability, but negatively affect the $V-T$ dependence of these polyethers. Alkyl groups lower the high melting points. *para* Derivatives have lower volatilities; for *ortho* products the volatilities are higher. Spontaneous ignition occurs between 550 and 600 °C and alkyl substitution reduces this by ca. 50 °C. With the usual elastomers swelling occurs.

The oxidation stability of polyphenyl ethers is only slightly lower than that of polyphenyls or tetraarylsilanes. Alkyl substituents reduce it. The thermal decomposition temperature is 465 °C. Short-chain substituents reduce it to below 380 °C and with higher alkyl groups it drops to below 350 °C, that is, to temperatures typical for aliphatic hydrocarbons. Trifluoromethyl groups decrease the thermal decomposition temperature to below 270 °C. Coke formation is low. It increases with alkyl substitution, particularly in the presence of methyl groups.

Polyphenyl ethers are the most radiation-resistant lubricants. At low temperatures radiation affects the viscosity more pronouncedly than at high temperatures. It increases viscosity, acidity, evaporation loss, corrosivity, and coke formation, but reduces flash and ignition point.

Between 200 and 300 °C the lubricating properties of polyphenyl ethers are reported to be comparable with those of mineral and ester oils and better than those of polysiloxanes and aromatic hydrocarbons. Alkylated polyphenyl ethers have better properties than the unsubstituted ethers. Polyphenyl ethers are suited as high-temperature or radiation-resistant hydraulic fluids and lubricants.

5.5.3. Polysiloxanes (Silicone Oils)

(→ Silicones, Chap. 3.)

Silicone oils suitable as lubricants are generally straight-chain polymers of the dimethylsiloxane (**4**) and phenylmethylsiloxane series (**5**). They have been described in detail [117], [118].

4

5

Methyl silicone oils are simply made from quartz and methanol in the end (Fig. 26), but commercial technology employs sophisticated steps, e.g., the so-called equilibration – treatment of a mixture of siloxanes of different molecular mass with strong acid or basic catalysts with the aim of achieving a narrow Gaussian molecular mass distribution [119].

Among the unique properties of silicone lubricating oils is their immiscibility with many organic fluids, the low temperature-dependence of their physical properties, and their physiological inertness. Silicone oils can be produced with very low pour points and high viscosity by increasing the asymmetry of the molecules, usually by partial replacement of the dimethylsilyl groups by phenylmethylsilyl groups. The density of silicone oils is in the region of that of water, those of dimethylsilicone oils are slightly below, those of phenylmethyl silicone oils slightly above.

The extremely low viscosity – temperature coefficients (*VTC*), < 0.6 for low-viscosity dimethylsilicone oils are mainly due to the extraordinary flexibility of their Si – O chains. Low to medium viscosity silicone oils have Newtonian behavior up to high shear rates, but with increasing viscosity the apparent viscosity decreases with increasing shear rate (pseudoplastic behavior). Compressibility and viscosity changes at high pressure depend strongly on the methyl-to-phenyl ratio of the silicone oils and are relatively large, again mainly because of the flexibility of their Si – O chains.

Figure 26. Preparation of dimethylsilicone oils

The thermal decomposition of silicone oils begins at ca. 300 °C. In general the decomposition products are not corrosive, but they lower the viscosity. Up to 200 °C the oxidation stability of silicone oils is superior to that of hydrocarbons, esters, and polyalkylene glycols. At higher temperature the formation of siloxyl and silyl radicals via cross-linking leads to the formation of polymer molecules and thus results in gels.

Some iron and cerium compounds are especially suitable as oxidation inhibitors for silicone oils. At elevated temperatures gel formation nevertheless occurs readily in the presence of selenium or tellurium. In the presence of chlorine even explosions are possible. Si – O bonds can also be broken by hydrolytic attack, but in contrast with silicic ester oils formation of silica or silicic acid gel does not occur.

The surface tension and the foaming tendency of silicone oils are much lower than those of mineral oils; silicone oils are, therefore, used as defoamers for the hydrocarbons.

Silicone oils can be found in all kinds of industrial and military installations. Dimethylsilicone oils are used as lubricants for bearings and gears with rolling friction. In sliding friction their performance depends on the metal pairs, they are used, for example, as lubricants for bronze or brass on aluminum. Silicone oils are among the best lubricants for plastic bearings, but in precision instrument applications spreading should be prevented by use of an epilamization agent. They are suitable lubricants for rubber parts, also, and also serve as switch and transformer oils. Silicone oils with higher phenyl substitution are mainly used for the lubrication of turbines, ball bearings, and all kinds of instrument, especially at high temperatures. Their radiation stability is also remarkable.

Silicone oils can be used as base oils for all kinds of lubricating *greases* [120].

5.6. Other Synthetic Base Oils

Of the following group of synthetic fluids that have been proposed as base oils for lubricants or that have been developed especially for that use, none has gained yet real economic or commercial importance in that area during the last 30 years, all still wait for their niche application, even though some have really astonishing properties.

Acetals have been investigated because of their high stability in alkaline media; they are, however, sensitive to acidic hydrolysis.

Adamantane derivatives, mainly the esters of 1,3-dihydroxy-5,7-dimethyladamantane, have been reported as being superior to the common dicarboxylic acid esters [122].

Aromatic amines, in particular their trialkylsilyl-substituted derivatives have been considered as lubricants because of their good heat resistance [121].

The performance of dialkylcarbonates, the diesters of carbonic acid, is similar to that of common dicarboxylic acid esters. They have been reported to be preferable to common ester with regard to lower toxicity and better seal compatibility [123]. In addition, no acid compounds are formed on decomposition.

Heterocyclic Boron, Nitrogen, and Phosphorus Compounds. Triazine derivatives such as melamine and cyanuric acid form the nuclei for fire-resistant and high-temperature lubricants [121], [122]. Polycarboranesiloxanes (**6**) have been reported to be comparable with silicone oils, but can be used at temperatures above 220 °C [124]. The fluorine-containing phosphazene derivatives (**7**) that have been developed mainly for the use in fire-resistant high-temperature hydraulic fluids [125] and for use as lubricity additives in perfluorinated polyethers [126], [127].

6

$R = C_6H_4F, C_6H_4{-}CF_3, \ldots$

7

Polyalkylene sulfides (polythioether oils) are polyalkylene glycols in which all C – O – C bonds are replaced by C – S – C bonds; they have good oxidation stability, and higher viscosities and lower pour points than the corresponding hydrocarbons [128].

Polyphenyl sulfides (polyphenyl thioethers, C-ethers) are polyphenyl ethers in which all C – O – C bonds are replaced by C – S – C bonds. This gives them lower pour points and better boundary lubrication properties, but reduced oxidative and thermal stability [129], [130].

Silahydrocarbons. Compared with their hydrocarbon analogs, silahydrocarbons, mainly tetraalkylsilanes have lower pour points, lower volatilities, higher *VI* values up to 155, and superior thermal stability [121, 131, 132]. They respond to antioxidants and antiwear additives in the same way as PAOs [133].

$R = CH_3, C_2H_5 \ldots C_{12}H_{25}$

Silicate esters, (ortho)silicic acid esters, have been known since the middle of the 19th century. Their properties differ strongly from those of siloxanes. Despite their good thermal stability and their low pour points their use is restricted to hydraulic, heat-transfer, and cooling fluids and to oils for automatic weapons because of their poor hydrolytic stability [134]. With the development of polysilicate clusters the shortcomings of the simple esters can, perhaps, be overcome [135].

5.7. Mixtures of Synthetic Lubricants

Today few lubricants contain only one base oil, firstly because mixing two or more base oils with different properties often leads to a lubricant with the desired performance, and secondly because many of the more polar synthetic base oils serve as additives in less polar oils, e.g., esters in hydrocarbons and vice versa. In thickened systems even immiscible base fluids like hydrocarbons and complex esters, perfluorinated ethers, or polyalkylene glycols can be combined.

6. Additives

Base fluids – mineral oil and also synthetic products – generally cannot satisfy the requirements of high performance lubricants without using the benefit of modern additive technology.

Additives can be classified into types that

1) influence the physical, e.g., $V-T$ characteristics, demulsibility, low temperature properties, etc., and chemical properties, e.g., oxidation stability, of the *base fluids*
2) affect primarily the *metal surfaces* modifying their physicochemical properties, e.g., reduction of friction, increase of EP behavior, wear protection, corrosion inhibition, etc.

Additives are used at contentrations from a few ppm (antifoam agents) up to 20 wt % or even more. They can assist each other (synergism) or they can lead to antagonistic effects. Some additives are multifunctional products that decrease the possibility of additives interfering with each other.

Of course, there are some properties that cannot be influenced by additives, e.g., volatility, air release properties, thermal stability, thermal conductivity, compressibility, or boiling point..

Although well balanced and optimized additive systems can improve the performance of lubricants enormously, the formulation of high performance lubricants requires also excellent high quality base fluids.

6.1. Antioxidants

The function of a lubricant is mostly limited by the aging of the lubricant base stock. Typical characteristics of aged lubricants are discoloration and a characteristic burnt odor. In advanced stages the viscosity will begin to rise significantly and acidic oxidation products are formed, which in turn may induce corrosion and lubricant problems. This aging process can be delayed tremendously by the use of antioxidants.

6.1.1. Mechanism of Oxidation and Antioxidants

The aging of lubricants can be differentiated into two processes: the oxidation process by reaction of the lubricant molecules with oxygen and the thermal decomposition (cracking) at high temperatures. In practice the oxidative aging of the lubricant is the dominating process which influences significantly the lifetime of the lubricant. Caused by steadily increased power density and reduced lubricant volumes (higher load : oil ratio) as well as extended service life in the last years, the thermal stress on the lubricant molecules grows constantly.

The oxidation of hydrocarbons can be described by the well-known free radical mechanism via alkyl and peroxy radicals [136]. The main reaction steps are shown in Figure 27.

Figure 27. Mechanism of autoxidation

The difference in reactivity of the miscellaneous radicals formed during autoxidation explains why linear and saturated hydrocarbons exhibit a much higher oxidation stability compared to branched, aromatic and unsaturated hydrocarbons.

The typical oxidation products that will be formed by these oxidation processes include alkyl hydroperoxides, dialkyl peroxides, alcohols, aldehydes, ketones, carboxylic acids, and esters. By polycondensation processes high molecular mass oxidation products are formed. These products are responsible for the typical viscosity increase of aged oil. Further polycondensation and polymerization of these oxidation products lead finally to oil-insoluble polymers that can be observed as sludge and varnish-like deposits.

Because of the acidic character of most of the oxidation products the danger of corrosion is increased. Also the attack of alkyl peroxy radicals on the metal surface may be responsible for corrosive wear. Furthermore such dissolved metals can form salts which also precipitate as sludge.

Nonhydrocarbon-based lubricants may behave totally different. Thus the aging of polyalkylene glycols will lead to a decrease of the viscosity caused by the decomposition of the polymeric structure.

Normally refined mineral base stocks contain traces of nitrogen-, sulfur- and oxygen-containing heterocycles as well as mercaptans, thioethers, and disulfides that may act as so-called 'natural antioxidants' or as pro-oxidants that will accelerate the oxidation of the lubricant. Usually the antioxidants are dominating thus providing a relatively good oxidation stability of the base oil. On the other hand hydrocracked base stocks (API group II and III) and synthetic lubricants like PAOs (API group IV) require a well balanced antioxidant combination in order to exploit the advantages of that kind of lubricants [137–139].

Antioxidants can be classified in primary antioxidants (radical scavengers) and secondary antioxidants (peroxide decomposers).

Radical scavengers compete successfully with the lubricant molecules in the reaction with reactive radicals of the propagation process. They react preferably with the radical oxidation products forming resonance-stabilized radicals that are so unreactive that they will stop the propagation of the autoxidation. Peroxide decomposers convert hydroperoxides into non-radical products thus also preventing the chain propagation reaction.

In finding the optimum synergistic antioxidant and metal deactivator combination the maximum delay of oil oxidation is achieved.

6.1.2. Compounds

Phenolic Derivatives (→ Antioxidants, Chap. 4.1.). Sterically hindered mono-, di- and polynuclear phenol derivatives belong to the most effective antioxidants acting as radical scavengers and are used in many applications. Typically the phenols are substituted in the 2 and 6 positions with tertiary alkyl groups. The most common substituent is the tertiary butyl group. The most simple derivatives are 2,6-di-*tert*-butylphenol (2,6-DTB) (**8**) and butylated hydroxytoluene, 2,6-di-*tert*-butyl-4-methylphenol (BHT) (**9**). The advantage of polynuclear phenols like 4,4′-methylenebis(2,6-di-*tert*-butylphenol) (**10**) or types with high-molecular-mass substituents in the 4 position is the reduced volatility due to the higher molecular mass that makes these products suitable for high temperature applications.

8

9

10

Aromatic Amines (→ Antioxidants, Chap. 4.2.). Oil-soluble secondary aromatic amines represent another important class of antioxidants that act as radical scavengers. Typical products are a large number of alkylated diphenylamines (**11**), *N*-phenyl-1-naphthylamine (PANA) (**12**) and the polymeric 2,2,4-trimethyldihydroquinoline (TMQ) (**13**). Because of its poor solubility in mineral oil the latter is commonly used in greases and polar lubricants.

11

12

$n = 9\text{-}10$

13

Compounds Containing Sulfur and Phosphorus (→ Antioxidants, Chap. 4.3.; Section 6.8). The most famous representatives of this group of additives are the zinc dithiophosphates which mainly act as radical scavengers [140]. Because of their multifunctional properties (antioxidant, antiwear additive, extreme pressure additive, corrosion inhibitor) zinc dithiophosphates are still being used as standard additives.

In addition, a large number of ashless dithiophosphoric acid derivatives, the so-called O,O,S-triesters, exist. These are reaction products of dithiophosphoric acid with olefins, cyclopentadiene, norbornadiene, α-pinene, polybutene, unsaturated esters like acrylic acid esters, malenic acid esters and other chemicals with activated double bonds [140]. All this additives show antiwear and also antioxidant properties, although their performance as antioxidant is not really as good as that of the metal dithiophosphates.

Organosulfur compounds are typical peroxide decomposers. Zinc and methylenebis(dialkyldithiocarbamates) have been found to be highly efficient [140].

Organophosphorus Compounds. Triaryl- and trialkylphosphites are the most common types of this group. They are not only peroxide decomposers, but they also can limit photodegradation. Because of their relatively poor hydrolytic stability their application is restricted to sterically hindered derivatives.

Other Compounds. Surprisingly organocopper compounds in combination with peroxide decomposers can act as antioxidants although catalytic quantities of copper ions usually act as pro-oxidants [140]. Overbased phenates and salicylates of magnesium and calcium behave as antioxidants at higher temperatures. Many other compounds have been proposed as antioxidants but none of these could gain a real relevance.

Synergistic Mixtures. Commonly several types of antioxidation and combinations of them are used. Well known is the synergistic effect of aminic and phenolic antioxidants. The combination of radical scavengers and peroxide

decomposers is called heterosynergism. So the combination of phenolic antioxidants with phosphites is known as highly efficient especially in hydrotreated base stock [141]. As metals may act as catalysts in the oxidation process typical rust inhibitors and metal passivators are also used as synergistic compounds (see also Section 6.10).

6.2. Viscosity Modifiers

6.2.1. *VI* Improvement Mechanisms

In the simplest case, a desired viscosity index can be achieved by mixing fluids with corresponding viscosity index improvers (*VII*s). But for a number of technical and commercial reasons, viscosity modifiers are often used.

Viscosity modifiers are chain-like polymeric molecules whose solubility depends on chain length, structure and chemical composition [142], [143]. As a rule, the base oil solubility of these polymer chains deteriorates when the temperature falls and improves with increasing temperature so that an increase in viscosity induced by viscosity modifiers also increases the viscosity index.

The absolute increase in viscosity and the *VI* depends on the molecular mass and the concentration of viscosity modifiers in the formulation [144]. In practice and depending on the projected application, molecular masses of 10 000 to 250 000 are used. Concentrations are usually between 3 and 25 wt %. As a result of their high molecular mass, viscosity modifiers are always dissolved in a base fluid.

Apart from their thickening effect which is schematically illustrated in Figure 28A as a function of molecular mass, shear stability serves as a second characteristic [145]. According to Figure 28B, increasing molecular mass reduces shear stability if the polymer concentration remains constant.

The reason for this effect is mechanically- or thermally-induced chain degradation [146]. Depending on the type and duration of the load, a number of different molecular sizes are created. The resulting drop in viscosity is described by the Permanent Shear Stability Index

$$\frac{[\text{KV before shearing}] - [\text{KV after shearing}]}{[\text{KV before shearing}] - [\text{KV of the base oil}]}$$

$$\text{e.g.,}\quad \frac{11\text{ct} - 8\text{ct}}{11\text{ct} - 5\text{ct}}$$

where KV denotes the kinematic viscosity.

If the relaxation time for the polymer chains is short (10^{-6} s), the high-molecular molecules adopt a temporary alignment. This drop in viscosity is described by the temporary shear stability index (TSSI).

Both values are of great importance to automotive applications, especially to engine, gear and hydraulic oils because the specified characteristics of such an oil do not just apply to the fresh oil but should remain throughout the drain interval. As the reduction in molecular mass in practice is overshadowed by oxidation and other effects, a series of laboratory tests have been established to characterize shear stability [147].

6.2.2. Structure and Chemistry of Viscosity Modifiers

The most important monomers for viscosity modifiers are listed in Table 7.

It is also possible to sort these polymers according to their supramolecular chain structure, independently of the base monomers used (Fig. 29).

dispersing. Dispersing viscosity modifiers are in principle the link to ashless dispersants which are discussed in Section 6.4.2.

6.3. Pour Point Depressants

With the exception of polyalkylated naphthalenes, pour point depressants (PPD) are closely linked to a series of viscosity modifiers. The major difference between pour point depressants and viscosity modifiers is their application concentration and the selection of monomer building blocks [148].

Although paraffin crystallization cannot be suppressed, the crystalline lattice and thus the morphology of the paraffin crystals can be significantly altered by PPDs. While polyacrylates and ethylene vinyl acetate copolymers are used for crude oils and petroleum, special polyalkyl methylacrylates are normally used for mineral oil-based formulations. Due to co-crystallization of paraffinic components in the

Figure 28. Thickening efficiency and shear stability of VMs

Table 7. Types of polymeric viscosity modifier

VM Type		Description	Main applications
OCP		olefin copolymers	engine and hydraulic oils
PAMA		polyalkyl (meth)acrylates	gear and hydraulic oils
PIB		polyisobutene	gear oils, raw material for ashless dispersants
SIP		hydrogenated styrene – isoprene copolymers	engine oils
SBR		hydrogenated styrene – butadiene copolymers	engine oils

Figure 29. Viscosity modifiers, chain structures, and monomer make-up

base oil and the polymer chain, the crystal morphology is altered. Instead of the needle-like paraffin crystals which rapidly cause paraffin gelation, densely packed, round crystals are formed which hardly affect flowing properties even at temperatures below the pour point. The corresponding polyalkyl methacrylates-PPDS are in principle, comb-like and contain $C_{12} - C_{24}$ paraffinic side chains [149]. By determining the polymer solubility and crystallization of paraffinic components in the base oil, the optimum PPD-mix and concentration can be determined for every base oil mixture. However, as a wide range of base oils are used in practice, standard products are often used which cover almost the entire spectrum. In such cases, efficiency is controlled via PPD concentration.

6.4. Detergents and Dispersants

Detergents and dispersants (DD), often called heavy-duty (HD) additives have been indispensable for the development of modern engine oils for gasoline and diesel combustion motors. These lubricants are especially severely stressed due to the high engine temperatures and the additional influence of aggressive blow-by gases of the combustion process. DD additives keep oil-insoluble combustion products in suspension and also prevent resinous and asphalt-like oxidation products from agglomerating into solid particles. These additives prevent oil thickening, sludge and varnish deposition on metal surfaces and corrosive wear.

The first detergent additives used were *metal-containing compounds*, often with high alkaline reserve.

To meet the dramatically increased requirements of modern high-performance engine oils new *ashless dispersants* with improved dispersing properties have been developed. As these ashless compounds possess also cleansing properties in fact there is no real difference between detergents and dispersants. Thus, it seems to be more appropriate to speak of metal-containing and ashless DD or HD additives [150], [151].

Mechanism of Action. Detergents and dispersants are generally molecules having a large oleophilic hydrocarbon 'tail' and a polar hydrophilic head group. The tail section serves as a solubilizer in the base fluid, while the polar group is attracted to contaminants in the lubricant. Solid contaminants are enveloped forming micelles whereby the nonpolar tails prevent the adhesion of polar soot particles on metal surfaces as well as the agglomeration into larger particles (peptidization).

6.4.1. Metal-Containing Compounds (Detergents)

Phenates represent an important class of detergents which are synthesized by reaction of alkylated phenols with elemental sulfur or sulfur chloride followed by the neutralization with metal (calcium, magnesium, barium) oxides or hydroxides. Calcium phenates are currently the

most widely used types. Basic calcium phenates can be produced by using an excess of the metal base. Beside their good dispersant properties they also possess greater acid neutralization potential.

Salicylates are generally prepared by carboxylation of alkylated phenols with subsequent formation of divalent metal salts. Typically also these products are overbased by an excess of metal carbonate (calcium and magnesium) to form highly basic detergents that are stabilized by micelle formation. Salicylates exhibit additional antioxidant properties and have proven effective in diesel engine oil formulations.

M = Ca, Mg

Thiophosphonates are produced by the reaction of polybutene (molecular mass from 500 to 1000) with phosphorus pentasulfide followed by hydrolysis and formation of metal (calcium, formerly also barium) salts.

The reaction products consist mainly of thiopyrophosphonates combined with thiophosphonates and phosphonates [152].

Sulfonates are metal salts of long-chain alkylarylsulfonic acids which can be divided into the petroleum and synthetic types. Beside their excellent anticorrosion properties (see Section 6.10.1) neutral and especially so-called overbased sulfonates with colloidally dispersed metal oxides or hydroxides (Fig. 30) additionally exhibit an excellent detergent and neutralization potential that makes them very cost-effective multifunctional DD additives for engine oils.

Calcium sulfonates are relatively cheap products with good general performance. Magnesium compounds have excellent anticorrosion properties but tend to form hard ash after thermal decomposition. Barium sulfonates are hardly used anymore due to toxicological concerns.

6.4.2. Ashless Dispersants (AD)

Ashless dispersants are generally derived from hydrocarbon polymers, usually from polybutenes with molecular masses of 500 to 3000 [153].

Polybutenes are thermally coupled with maleic anhydride (MA) to give alkylsuccinic anhydrides. In a further reaction step oligomeric aminoalkylenes are added to the anhydride to form thermally stable imides. By using suitable raw materials and reaction control, this two-stage, one-pot reaction can produce a variety of products. A sample reaction scheme is shown in Figure 31.

Novel developments are monofunctional and bifunctional polyisobutylene succinic anhydrides (PIBSAs). Apart from the bifunctional amines (triethylene tetramines, tetraethylene pentamines), alcohols such as pentaerythritols are used to improve the base character and the resulting interactions with elastomers.

The dispersion of oxidation, nitration and soot particles can be controlled by product mixture and the purity of the components.

Equally chlorine-free alternatives are low-molecular-mass, dispersant PAMAS. Contrary to hydrocarbon-based oligomers, the dispersing units are spread along the chains, whereby the type of dispersing groups can vary greatly [154]. Current research reports advantages of these type of AD with regard to soot dispersing and improved fuel efficiency characteristics [155].

6.5. Antifoam Agents

The foaming of lubricants is a very undesirable effect that can cause enhanced oxidation by the intensive mixing with air, cavitation damage as well as insufficient oil transport in circulation systems that can even lead to lack of lubrication. Beside negative constructive influences the foaming tendency is influenced by the surface tension of the base oil and especially by the presence of surface-active substances such as detergents, corrosion inhibitors and other ionic compounds.

Two types of foam can be discriminated:

Surface foam can be controlled by antifoam agents. Effective defoamers are usually not solu-

Figure 30. Model of the structure of overbased sulfonates

ble in the base oil and therefore have to be finely dispersed. The particle size of the dispersed defoamers should be smaller than 100 µm or even smaller than 10 µm [156].

The *inner foam* refers to finely dispersed air bubbles in the lubricant that can form very stable dispersions. Unfortunately the common defoamers that control the surface foam tend to stabilize the inner foam. Generally the air release properties of lubricants cannot be improved by additives. Lubricants which need excellent air release properties, e.g., turbine oils have to be formulated using specially selected base oils and additives.

Silicone Defoamers. Liquid silicones, especially linear and cyclic polydimethylsiloxanes, are the most efficient antifoam agents at very low concentrations of 1 to max. 100 mg/kg. To guarantee a stable dispersion silicones usually are predissolved in aromatic solvents.

Compared to other additives silicone defoamers have the disadvantage of being particularly easily carried out of the lubricant due to their insolubility and their strong affinity to polar metal surfaces.

Silicone-free defoamers are being used more and more in many applications, especially in metalworking processes. Cutting fluids and hydraulic fluids have to be silicone-free to guarantee the subsequent application of paints or lacquers on the workpieces.

The main representatives of silicone-free defoamers are special poly(ethylene glycols) and miscellaneous organic copolymers. Also tributylphosphate has been proposed as antifoam agent.

6.6. Demulsifiers

Most of the industrial oils in circulation systems (hydraulic, gear, turbine and compressor oils) require good or excellent demulsification properties to separate water from the lubricating system. Without demulsifiers lubricating oils can form relatively stable water-in-oil emulsions.

In principle, all surface-active substances are suitable demulsifiers. One of the first known types have been alkaline-earth metal salts of organic sulfonic acids particularly barium and calcium dinonylnaphthenesulfonates. Nowadays

Figure 31. Reaction mechanism for the manufacture of ashless dispersants

special poly(ethylene glycols) and other ethoxylated substances are used.

Surprisingly the same class of chemical substances is used as emulsifiers. Here the molecular mass, the degree of ethoxylation and the treat rate are very important to guarantee the demulsifying properties.

6.7. Dyes

For marketing, identification or leak detection purposes some lubricants contain dyes [157]. Most of these substances are solids which often are suspended in mineral oil or dissolved in aromatic solvents to make their handling easier.

Generally oil-soluble azo dyes are used. Some of these products may be removed in the near future because they have to be labeled as potential carcinogenes.

Fluorescent dyes are typically used to detect leaks under UV light when the coloration of lubricants is not appreciated.

6.8. Antiwear and Extreme Pressure Additives

When two contacting parts of a machinery start to move and the hydrodynamic lubrication has not yet build up or in the case of severe stress and strong forces the lubricating system runs in the area of mixed friction. In this case antiwear (AW) and extreme pressure (EP) additives are necessary in any metalworking fluid, engine oil, hydraulic fluid or lubricating grease to prevent welding of the moving parts respectively to reduce wear.

Function of AW/EP Additives. Because of their polar structure AW/EP additives form

layers on the metal surface by adsorption or chemisorption that guarantees their immediate availability in the case of mixed friction conditions. When the hydrodynamic lubricating film is not yet or no longer valid, temperature will increase and the AW and EP additives can react with the metal surface forming tribochemical reaction layers (iron phosphides, sulfides, sulfates, oxides and carbides – depending on the chemistry of the additive) that will prevent direct contact between the sliding metals.

AW additives are mainly designed to reduce wear when the running system is exposed to moderate stress whereas EP additives are much more reactive and are used when the stress of the system is very high in order to prevent the welding of the moving parts that otherwise would lead to severe damage.

Phosphorus Compounds. Under condition of medium stress organic phosphorus compounds work excellent as antiwear additives.

Most of these additives are neutral and acidic phosphoric acid esters, their metal or amine salts or amides. As the acidic form of these compounds is the most reactive one, the reactivity decreases with the degree of neutralization.

Tricresylphosphate (TCP) is the most important neutral phosphoric acid triester. For toxicological reasons TCP should be free of *o*-cresol.

Amine salts of mixtures of mono- and dialkyl phosphoric acid partial esters are highly efficient FZG boosters. Some types exhibit additional anticorrosion properties.

Ethoxylated mono- and dialkylphosphoric acids are even more polar due to their hydrophilic structure what makes them more efficient.

Also *phosphites* could gain some signification. Because of the inherent hydrolytic instability of this chemical group in practice only sterically hindered derivatives like triarylphosphites and long chain trialkylphosphites are used for some applications.

Compounds Containing Sulfur and Phosphorus. The most important additives of this group are the zinc dialkyldithiophosphates (ZnDTP) [159]. They are synthesized by reaction of primary and secondary alcohols ($C_3 - C_{12}$) or alkylated phenols with phosphorus(V)sulfide followed by neutralization of the resulting dialkyldithiophosphoric acids with zinc oxide. Beside the neutral species also basic ZnDTPs can be obtained when the neutralization is done with an excess of zinc oxide.

Zinc dialkyldithiophosphate/
zinc dialryldithiophosphate

ZnDTPs based on isopropanol or *n*-butanol are solids, whereas mixtures of short and long chain alcohols are liquid. The thermal and hydrolytic stability of ZnDTPs and thus their reactivity (AW/EP-performance) can be influenced by the structure of the alkyl groups. So the thermal stability increases with the chain length of the alkyl groups and their structure in the sequence secondary, primary and aromatic. By carefully directed alcohol composition the specific requirements of different applications can selectively be adjusted. Beside excellent antiwear and extreme pressure properties ZnDTPs are also efficient antioxidants and even metal passivators. This multifunctional properties makes them the widest spread cost effective additive group that is used nowadays in huge quantities in engine oils, shock absorber oils and hydraulic fluids.

Beside ZnDTPs also *ammonium, antimony, and molybdenum dialkyldithiophosphates* are known. The latter are effective antiwear additives with remarkable friction reducing properties and excellent antioxidant behavior.

Ashless dialkyldithiophosphoric acid-O,O,S-triesters have higher hydrolytic stability than the corresponding acids, but poorer antioxidant properties. Similar to the ZnDTPs the reactivity can be influenced by variation of the organic substituents.

Triphenylphosphorothionate (TPPT) is distinguished by its extraordinary thermal stability what makes it suited for high temperature lubrication.

Compounds Containing Sulfur and Nitrogen.

Zinc-bis(diamyldithiocarbamate) and the ashless methylene-bis(di-*n*-butyldithiocarbamate) are highly effective EP additives and excellent antioxidants. Beside these main species also antimony and tungsten derivatives are known. Dithiocarbamates are predominantly used in lubricating greases and to some extent in gear oil formulations.

Dialkyl-2,5-dimercapto-1,3,4-thiadiazole (DMTD) derivatives (see Section 6.10) are usually classified as metal passivators and sulfur scavengers, but they also exhibit excellent EP properties. The use of thiadiazoles and dithiocarbamates is limited by their relatively high price.

Sulfur Compounds. From the early days of lubrication until now elementary sulfur has been dissolved directly in mineral oil (up to 1.5 %) to improve the EP properties of metal working fluids. Oil-soluble organic sulfur compounds, the so-called sulfur carriers, of the general formula $R-S_x-R$ offer improved solubility and exact control about the reactivity of the sulfur.

Inactive and active sulfur carriers can be differentiated. The inactive types with predominantly disulfide bridges ($x = 2$) possess relatively stable C – S bonds which will react at elevated temperatures only. The active forms with x between 3 and 5 (so-called pentasulfides) are much more reactive as the sulfur of the relatively labile polysulfide bridges can easily be made available even at low temperatures. Moreover numerous sulfur carriers with specific distribution of the different polysulfide bridges ($x = 1-5$) are used to cover the whole field of application with its varying stress requirements. The mechanism of action begins with physical adsorption followed by chemisorption and finally cleavage of the sulfur – carbon bond and reaction of sulfur with the metal surface (Fig. 32). Generally this reaction takes place at temperatures over 600 °C [158].

Active sulfur carriers are excellent EP additives. Because of the high reactivity with nonferrous metals active sulfur carriers cannot be used in the machining of nonferrous metals. Inactive sulfur carriers need higher temperatures to set the sulfur free. Therefore they are much more compatible with nonferrous metals and show to some extent antiwear properties.

The polarity and thus the affinity to the metal surface is determined by the organic substituents.

Sulfurized hydrocarbons are obtained by direct sulfurization of olefins (e.g., diisobutene, terpenes) with elementary sulfur in the presence of H_2S, their reaction with dichlorodisulfide or oxidation of mercaptans to disulfides. The first method will lead to products with high sulfur contents up to 45 %. The other will form inactive sulfur carriers that are predominantly used in gear oils and mild metalworking fluids (cutting fluids). Active pentasulfides are used for severe machining processes, e.g., broaching.

Sulfurized fatty oils and fatty acid esters are produced by sulfurization of the unsaturated raw materials with sulfur (dark colored products) or with sulfur in the presence of H_2S to obtain light colored products that are used predominantly in modern lubricants instead of the formerly used sperm oil products. The combination of sulfur with the friction reducing properties of the fatty raw materials leads to excellent EP additives with high load carrying capacity in the four ball testing machine. Sulfurized fatty acid methyl esters will lead to products with low viscosities that are used, e.g., for deep-hole drilling.

PEP Additives. Overbased sulfonates, especially calcium and sodium salts, can be used as highly efficient boosters in combination with active sulfur carriers to formulate metal working fluids with extremely high load carrying behavior. These overbased products are called PEPs (passive EP).

Chlorine Compounds. Dispite their excellent AW/EP properties, chlorine compounds are being increasingly replaced by other additives for environmental and toxicological reasons.

Solid Lubricating Compounds (see Chap. 15). Mainly finely ground powders of *graphite* and *molybdenum disulfide* and their dispersions are used as solid additives. Solid lubricants possess excellent emergency running

Figure 32. Mechanism of sulfur carriers under extreme pressure conditions

properties when the oil supply is breaking down. Also for extreme high temperature applications solid lubricating compounds are used due to their high thermal stability. Other compounds that are used especially in lubricating greases are *polytetrafluoroethylene, calcium hydroxide* and *zinc sulfide*.

6.9. Friction Modifiers

In the case of liquid (hydrodynamic) lubrication friction can be reduced only by the use of base oils with lower friction coefficients and lower viscosity respectively high viscosity indices. In the area of low slide velocities, moderately increased loads and low viscosities at higher temperatures the liquid lubrication can easily proceed to mixed friction conditions. In this case so-called friction modifiers have to be used to prevent stick – slip oscillations and noises by reducing frictional forces. They work at temperatures where AW and EP additives are not yet reactive. Therefore, friction modifiers (FM) can be regarded as mild AW or EP additives working at moderate temperatures and loads in the area of beginning mixed friction.

Friction modifiers can be classified into different groups regarding their function [160]: mechanically working FMs (solid lubricating compounds, e.g., molybdenum disulfide, graphite, PTFE, polyamide, polyimide, fluorinated graphite), adsorption layers forming FMs (e.g., long-chain carboxylic acids, fatty acid esters, ethers, alcohols, amines, amides, imides), tribochemical reaction layers forming FMs (saturated fatty acids, phosphoric and thiophosphoric acid esters, xanthates, sulfurized fatty acids), friction polymer-forming FMs (ethoxylated dicarboxylic acid monoesters, dialkyl phthalates, methacrylates, unsaturated fatty acids, sulfurized olefins) and organometallic compounds (molybdenum compounds like molybdenum dithiophosphates, molybdenum dithiocarbamates, their synergistic combination with ZnDTPs, copper containing organic compounds).

Typical applications of friction modifiers are modern fuel economy oils, slide way oils, automatic transmission fluids (ATF) that contain so-called anti-squawk additives, and lubricants for limited-slip axles that contain so-called antichatter additives.

6.10. Corrosion Inhibitors

Anticorrosion additives are molecules with long alkyl chains and polar groups that can be adsorbed on the metal surface forming densely packed, hydrophobic layers. The adsorption mechanism can base on a physical or chemical interaction of the polar anticorrosion additive with the metal surface [161].

Because of this high surface activity, anticorrosion additives compete with other polar additives like antiwear and extreme pressure additives for the metal surface and can therefore reduce their efficiency. Thus a FZG damage load stage of > 12 can be reduced down to a damage load stage of 8 if highly efficient and polar anticorrosion additives are added.

Corrosion inhibitors can be divided into two main groups: antirust additives for the protection of ferrous metals and metal passivators for nonferrous metals.

6.10.1. Antirust Additives

Sulfonates. *Petroleum sulfonates* (mahogany sulfonates) are byproducts at the pro-

duction of white oils by treatment with oleum. The resulting acid tar contains long-chain alkylarylsulfonic acids that can be neutralized with lyes. Sodium sulfonates with low molecular masses (below approx. 450) are typically used as low-priced emulsifiers and detergents with additional anticorrosion properties in water based metal working fluids, engine oils and rust preventatives. Sulfonates with higher molecular masses are highly efficient corrosion inhibitors especially when based on divalent cations like calcium, magnesium, and barium. The importance of the barium compounds decreasing constantly due to toxicological and ecotoxicological concerns.

Nowadays *synthetic alkylbenzene sulfonates* are used preferably in spite of a higher price level due to their higher and more constant quality. They are reaction products of specifically designed monoalkylbenzenesulfonic acids (typically C_{24} alkyl groups) and dialkylbenzenesulfonic acids (typically two C_{12} alkyl groups) with alkaline and alkaline-earth metal hydroxides.

A special group of synthetic sulfonates are the *dinonylnaphthenesulfonates* of which the neutral calcium and barium salts are distinguished by additional demulsifying properties and a good compatibility with EP additives.

Beside the neutral or only slightly basic sulfonates *overbased sulfonates* with high alkaline reserve (TBN 100 to 400 mg KOH/g) play an important role especially in the formulation of engine oils. There they exhibit detergent properties and can neutralize acidic oxidation products.

Carboxylic Acid Derivatives. *Lanolin* (wool fat) and salts of the lanolin fatty acid mostly in combination with sulfonates have long been known as corrosion inhibitors in rust preventatives. *Oxidized paraffins* with their high content of hydroxy- and oxocarboxylic acids are still used for that purpose.

Zinc naphthenates are especially used in lubricating greases.

Alkylated succinic acids, their partial esters and half amides are known as highly efficient, not emulsifying antirust additives even at very low treat rates of 0.01 to 0.05 %. Therefore these additives are used preferably in turbine oils and hydraulic fluids. *4-Nonylphenoxyacetic acid* and derivatives have a similar performance.

Another widespread group are *amides and imides* of saturated and unsaturated fatty acids. The best known product of this type is *N-acylsarcosine* that shows a strong synergistic effect with *imidazoline derivatives*. Additionally these additives have good water-displacing properties.

Amine Neutralized Alkylphosphoric Acid Partial Esters. Some special amine salts of mono- or dialkylphosphoric acid partial esters exhibit excellent anticorrosion properties in addition to their highly efficient antiwear properties [162]. Because of the well-known antagonism of anticorrosion and antiwear additives this behavior makes them one of the mostly used components in ashless industrial oils.

Vapor phase corrosion inhibitors (VCIs) for closed systems are substances with high affinity to metal surfaces and relatively high vapor pressure to guarantee their availability on parts that are not steadily in direct contact with the corrosion inhibited lubricant. The mostly used product group for this application are amines. *Morpholine*, *dicyclohexylamine*, and *diethanolamine* have proved to be highly efficient for that purpose. Because of toxicological concerns, that refer mainly to the nitrosamine forming potential of secondary amines, these products are being partly substituted by tertiary amines like *diethanolmethylamine* and similar products.

Another group of oil soluble VCIs are low molecular *carboxylic acids* (*n-C_8 to n-C_{10}*).

6.10.2. Metal Passivators

Metal passivators can be classified into three groups: film forming compounds, complex forming chelating agents, and sulfur scavengers.

Figure 33. Function of benzotriazole as film forming agent

The fundamental function of the film forming types consists in the building of passivating protective layers on the nonferrous metal surface thus preventing the solubilization of metal ions that would work as pro-oxidants. The complex forming agents are able to build oil-soluble complexes with significantly reduced catalytic activity regarding the influence of nonferrous metal ions on the oxidative aging process of lubricants. Sulfur scavengers are even able to scavenge corrosive sulfur by integrating it into their molecular structure. Mechanism and function of these three types of metal passivator are shown in Figures 33, 34, and 35.

Figure 34. Function of *N,N′*-disalicylidene-propylenediamine as chelating agent

Metal passivators in combination with antioxidants show strong synergistic effects as they prevent the formation of copper ions respectively suppress their behavior as pro-oxidants. Thus these additives are used in nearly every formulation of modern lubricants.

The mostly used metal passivators are *benzotriazole* and *tolyltriazole* as well as their alkylated liquid derivatives with improved solubility. Typical treat rates of these film forming passivators are between 0.005 and 0.03 %.

Furthermore *2-mercaptobenzothiazole* (reduced importance) and especially *2,5-dimercapto-1,3,4-thiadiazole* derivatives are used as highly efficient film forming passivators. The later can also act as sulfur scavenger by building in sulfur into the alkyl – sulfur – thiadiazol bonds (see Fig. 35).

N,N′-disalicylidenealkylendiamines (where 'alkylen' is ethylene or propylene) belong to the group of chelating agents. Beside their EP and antiwear properties *zinc dialkyldithiophosphates* and *dialkyldithiocarbamates* have some metal-passivating properties (see Section 6.8).

7. Lubricants in the Environment

Lubricants and functional fluids are omnipresent due to their widespread use and they thus pollute the environment in small, widely-spread amounts and rarely in large, localized quantities.

Normally biodegradability of at least 60 % according to OECD 301 or 80 % according to CEC L-33-A-93 is considered as main objective criteria for 'Bio-Lubricants'. But the other criteria will get more and more importance in the near future.

7.1. Current Situation

Every year, about 40 – 50 % of the approximately 5×10^6 t of used lubricants in Europe end up polluting the environment. This is either technically desired (total-loss lubrication) or follows leaks, or other problems.

The environmental damage caused by mineral oil-based lubricants is largely caused by the

Figure 35. Function of dialkyl-2,5-dimercapto-1,3,4-thiadiazole as sulfur scavenger

approximately 40 % of lubricants which are not properly disposed of. This figures include total-loss applications, the residual oil in about 90 million oil cans and 20×10^6 oil filters, spillages during topping-up, leaks, drips from separated oil-line and hydraulic couplings, accident losses and all manner of emission losses (CONCAWE Report no. 5/96).

Even though mineral oil products can be relatively rapidly biodegraded by the microorganisms present in nature, these natural degrading systems are exhausted by the volume of the losses.

In the past, mineral oil-based products were used almost exclusively. Leakages and other causes allowed a part of these lubricants to pollute the environment. The problem has spurred society and politics into action, reflected by diverse legislation and recommendations as well as the issuing of environmental awards to products which cause less damage. The use of environmentally friendly materials and substances will play an increasingly important part in the scope and procedures of the EU Eco Audit.

Technically, and disregarding development and overall costs, more than 90 % of all lubricants could be made rapidly biodegradable. However, this change will only take place if the ecological benefits of using renewable raw materials is made clear and best of all, quantified in monetary terms.

7.1.1. Economic Consequences and Substitution Potential

In Germany the selection of rapidly biodegradable lubricants, especially those classified as 'not water pollutant' reduce the expense of oil spillages or disposal as well as the cost of complying with health and safety regulations to a minimum. Compared to mineral oil-based products, the selection of low-evaporation ester and vegetable oil-based lubricants can allow lower viscosities to be used. This enables faster machining and cuts drag-out losses. This, in turn, increases economy, increases productivity and generates product optimization.

The vast majority of rapidly biodegradable lubricants currently on the market are based on saturated or unsaturated ester oils. The acids required for esterification are mostly from vegetable oils. Compared to equivalent mineral oils, ester oils are significantly more expensive. This is a major barrier to the wider acceptance of such oils. But the overall cost of a lubricant results from the interaction between the following characteristics (in alphabetical order):

- Aging and temperature stability
- Disposal costs
- Machine compatibility (multifunctional oil)
- Machine investments
- Maintenance measures
- Oil change intervals
- Operating costs
- Reconditioning possibilities
- Reduction in storage costs
- Reduction in emission reduction measures
- Reduction in the cost of preventative health and safety measures
- Risk minimization and lower clean-up costs after spillages
- Simpler plant license procurement

Completely new mix of economic aspects can result from every new application. In particular, the use of fully saturated synthetic esters offers a number of opportunities. Pure vegetable oil for-

mulations are now only used for lower demands, for example total-loss chain saw or mold release oils and some types of greases.

7.1.2. Agriculture, Economy, and Politics

The world market price of vegetable oils is largely influenced by the price of soybeans. Since half of the world's soy production comes from the USA, vegetable oil prices are heavily dependent on the size of US soy harvest. On the German market, the price of rapeseed (in Hamburg, Rostock or Mannheim) is particularly significant.

Increasing sales of environmentally harmless lubricants could have a positive effect on prices and this, in turn, would make such lubricants even more interesting.

Until now, in Europe rapeseed and sunflower oil as lubricant base oils have been in the forefront because of the following reasons:

- They are abundantly available
- Their thermal oxidation stability are acceptable in some applications
- Their flowing properties are better than those of other vegetable oils

The disadvantages of the abovementioned vegetable oils are:

- The oxidation, hydrolytic and thermal stability of vegetable oils is not adequate to allow their use in circulating systems and
- High-performance additives for vegetable oils have not undergone sufficient development, especially those which are ecotoxicologically safe and ecologically harmless.

Apart from pure vegetable oils, oleochemical esters can also be used because their thermal-oxidation stability compared to rapeseed oil opens up a wider field of applications. However, these products are considerably more expensive, a factor which in turn, limits their use.

In 1999, nevertheless, 20 000 ha of rapeseed were cultivated in Germany only for application in lubricants. This corresponds to a volume of nearly 20 000 t/a from which an approximately similar quantity of lubricating or hydraulic oils are manufactured. It can be assumed that about 20 000 to 25 000 t of oleochemical esters are used for biodegradable lubricants per year so that biodegradable lubricants account for just over 4 % of all lubricants (Germany 1999).

In Germany as most important market for biodegradable lubricants today a number of political initiatives were started in recent years, of which some were included in two comprehensive reports which were submitted to the German parliament.

- Resolution dated June 16, 1994: Measures to promote the use of rapidly biodegradable lubricants and hydraulic fluids
- Resolution dated November 28, 1995: News from the Federal Ministry for Food, Agriculture and Forestry: 'Report on the use of rapidly biodegradable lubricants and hydraulic fluids and measures taken by the Government' (New Edition 1999)
- Regulation for introduction of environmental friendly lubricants to market (June 2000): This program supports the substitution of mineral based lubricants by ester based products.

The use of environmentally friendly fluids is mandatory in the public sector.

Research and Development on ecologically harmless fluids and the clarification of unanswered questions is sponsored through projects.

7.2. Biodegradable Base Oils for Lubricants

The most important biodegradable base oils are different types of ester oil, e.g.:

- Vegetable oil from harvestable raw materials, for example rapeseed or sunflower oil
- Semisaturated, transesterified ester oils with natural fatty acids, for example trimethyolepropane trioleate
- Fully saturated, synthetic esters based on chemical modified vegetable oils or mineral oil, for example, diisotridecyl adipate

Other in principle biodegradable base oils mostly are not considered as 'environmental friendly lubricants' because of their petrochemical origin:

- Poly(alkylene glycols) (PAG)
- Low viscosity polyalphaolefins (PAO 2)
- Some special types of synthetic hydrocarbon up to a viscosity of 6 mm^2/s at 100 °C

Natural Fats and Oils (Triglycerides). The worldwide market for natural oils amounts to 100×10^6 t/a. The dominant crops are soybean (Northern America), palm (SE Asia, Southern America) and rapeseed oil (Europe).

In Germany, nearly 900 000 t vegetable oils are used only for industrial applications – with increasing numbers in the last years. The main part today is transesterified to biodiesel (rapeseed methyl ester).

Apart from the abovementioned environmental aspects, the use of natural oils also has an agri-political benefit of enabling the agricultural industry to shift its production to technical raw materials. The lubricants industry has invested significant sums of money in developing and marketing biodegradable lubricants.

Natural fatty oils such as castor oil, palm oil, rapeseed oil, soybean oil, sunflower oil, lard, degras and sperm oil, i.e., triglycerides of more or less unsaturated fatty acids, have been used in lubricants for years. These base oils are biodegradable and, compared to mineral oils, have excellent tribological properties (low friction coefficient, good wear protection). Their range of use is limited by lower stability against thermal oxidative and hydrolytic stress and partly inferior cold flow properties. These limits can be improved gradually either with additives, or with the selection, cultivation or genetically modification of new types of plants. With new types of 'High oleic sunflower oils' (HOSO) with an amount of oleic acid of more than 90 % it seems possible to formulate oils for higher performance levels.

7.2.1. Synthetic Esters

The collective name 'synthetic esters' covers a broad range of chemicals with different qualities and prices. For the development of environmentally acceptable lubricants, esters have to be selected which fulfil the ecological requirements and have more favorable properties than natural fatty oils.

These properties are mainly thermal-oxidative resistance, better low temperature behavior and better resistance to hydrolysis.

At present, polyol esters such as trimethylolpropane esters (TMP esters) or glycerol trioleate dominate. The basis of these are mainly alcohols from petrochemical and oleochemical origin and fatty acids derived from natural oils.

In regard to hydrolytic stability, 'normal' polyol esters differ only slightly from rapeseed oil; the difference in oxidation resistance is much greater. Both characteristics are significantly improved with complex esters of polyols and saturated fatty acids. Normally an improvement in hydrolytic stability worsens the base fluid's biodegradability.

The most important chemical reactions to improve the properties of esters are transesterification, (selective) hydrogenation, ozonolysis, dimerization.

7.2.2. Polyalkylene Glycols (see Section 5.4)

Polyethylene glycols (PEG) are biodegradable. They are not miscible with mineral oils or esters, but are water-soluble which, at the present time, is considered to be a disadvantage. If PEG is released through a leak or an accident, it will migrate quickly in the ground or in the water.

The chemical industry is attempting to develop biodegradable, non-water-soluble PAGs. These could be alternatives to esters.

7.2.3. Polyalphaolefins (see Section 5.1.1)

Low viscous polyalphaolefins (PAO 2) are biodegradable. These base stocks have only limited application in the formulation of lubricants. The new types of biodegradable, higher viscosity synthetic hydrocarbons may have a greater influence in the near future.

7.2.4. Relevant Properties of Biodegradable Base Oils

Evaporation Loss. The evaporation loss of esters and vegetable oils is very low. The lower evaporation loss of ester oils has great advantages for example in regard to emissions from machine tools in metalworking and for the emissions, especially the particle emissions, of internal combustion engines.

Viscosity – Temperature Behavior. Using an ester instead of a mineral oil improves the viscosity – temperature behavior of a lubricant. The higher viscosity index (*VI*) of an ester results in a wider temperature range in application but with the recommended working viscosity. Also the higher *VI* can lead to polymer-free multigrade lubricants with improved shear stability.

Boundary Lubrication. Most vegetable oils, synthetic esters and glycols display excellent lubricity in boundary lubrication conditions. Because of their high degree of polarity these lubricants are superior to mineral oil based lubricants. This has been proven by a series of tests. Experimental investigations on twin disk test rigs showed that the friction coefficient of vegetable oils, synthetic esters and glycols is half that of mineral oils:

Figure 36 compares feiction coefficients of a mineral oil and a TMP ester of the same viscosity grade. As can be seen, the friction coefficient for this ester is half that of a mineral oil.

7.3. Additives (see also Chap. 6)

Extreme Pressure/Antiwear Additives. Most vegetable oils and synthetic esters used in lubricants display have a high degree of polarity. This characteristic results in better lubricity than mineral oils in boundary conditions. Sulfurized fatty materials are environmentally friendly EP additives. Sulfur as an additive in esters provides an AW effect. Sulfur carriers with 15 % total sulfur and 5 % active sulfur have proven effective in rapidly biodegradable esters and vegetable oils.

Corrosion Inhibitors. Vegetable oils and synthetic esters show a high polarity. This also applies to corrosion inhibitors and can result in a competitive reaction on the metal surface.

Special calcium sulfonates, succinic acid derivatives or ashless sulfonates can be used to provide corrosion prevention.

Antioxidants. Special phenolic and aminic materials are suitable antioxidants for the formulation of biodegradable lubricants.

7.4. Products (Examples)

Because of their physical properties, refined, chemically unchanged vegetable oils can be used as alternatives to petroleum products in a large number of lubricants. Compared to mineral oils, their performance in most applications is limited by their relatively poor aging resistance. The reasons for this are the unsaturated hydrocarbon chains in the natural fatty acids and the easy hydrolysis of the ester compounds.

Vegetable oils, at present, are primarily used for total-loss applications and products with relatively low technical specifications. At face value, using rapeseed oil as a basis for engine oils does not appear very promising – the present operating conditions of engine oils cannot be satisfied by chemically unmodified vegetable oils.

Over many years the development in the lubricants market had the main aim to formulate products for 'long oil drain intervals' or for lifetime. This was not possible with vegetable oil. But today the opposite development can be recognized in some applications – the substitution of circulating oils by total-loss lubricants:

- Example 1: Minimum Quantity Lubrication in metalworking
- Example 2: Die-casting and forming instead of cutting and grinding
- Example 3: Oil-refreshing systems for lubrication of four-stroke engines

These ideas are not primarily intended for use of chemically unchanged vegetable oils in new applications. The main idea behind all examples is the lower overall impact of lubricants and their degradation products on the environment by use of total-loss lubricants.

For four-stroke engines, a novel lubrication concept for diesel engines was developed which counteracts the relatively poor aging resistance of vegetable oils by continuous refreshing (Plantotronic system). This has permitted the use of rapeseed and sunflower oils for engine lubrication. In this lubrication system, used oil is gradually burned along with the fuel itself without negatively influencing emission values.

The concept can be seen as a way of continuously refreshing a vegetable-based engine oil or as a way of performing a continuous oil change. Combustion in the engine was only made possible by the use of low-additive vegetable oils –

Figure 36. Friction coefficients of two base fluids as function of slip

Figure 37. Scheme of lubrication points in an engine

burning conventional oils seems highly contentious considering the additives commonly used in such oils. The use of vegetable oils for engine lubrication depends on the progressive burning of used engine oil with the fuel. The advantage of the oil refreshing method is that chemically unmodified, low additivated vegetable oils can be used and that no waste oil has to be disposed of. Another advantage is the automated oil-change, which helps to reduce the maintenance costs especially for stationary engines (power plants).

8. Lubricants for Internal Combustion Engines

8.1. Four-Stroke Engine Oils

Technically and commercially, engine oils are the number 1 among lubricants and functional fluids; on the global lubricants market, they account for more than 60 %.

While demand in Europe is more or less stagnating and will decline slightly in the foreseeable future in spite of increasing vehicle registrations, there is still considerable growth potential in Southeast Asia and third world threshold countries (China, India, Korea etc.) [201].

8.1.1. General Overview

Historically the development of engine oils over the last 50 years has been focussed on the specifications issued by the international automobile industry. Starting with the first specifications published by the US Army (MIL specs), today there are three internationally recognized sets of minimum requirements. In Europe, these are ACEA, in the USA API, and ILSAC in Asia. Details of these specifications can be found in Section 8.1.3.

In principle, all specifications reflect the successive adaptation of oil qualities to developments in engine design. Back in the 1950s, monogrades dominated the engine oil market. The viscosity of these oils was matched to the prevailing ambient temperature and therefore had to be changed between summer and winter. The 1960s saw the development of mineral oil-based multigrades, i.e., combined summer and winter oils, initially high-viscosity types (SAE 20W-50) and later the present standard 15W-40. Base oil distillation and refining processes caught up with the new viscosity and performance requirements (see Chap. 4). This led to new qualities with comparatively low evaporation losses and optimized cold flowing properties. Semisynthetic, and since the 1920s, fully synthetic oils have dominated the premium-quality market, especially in the passenger car sector. Since the 1990s, a niche for environmentally friendly, biodegradable products has been created in the German-speaking market [202].

8.1.1.1. Fundamental Principles

Engine oils have to fulfil a wide range of functions in engines. The purely tribological task consists of guaranteeing the functional reliability of all friction points in all operating conditions (Fig. 37). In addition, engine oils have to perform a number of other functions. This begins with the sealing the cylinder and ends with the transport of sludge, soot, and abraded particles to the oil filter.

Starting with the tribological functions, the three classic sections of the Stribeck graph are satisfied, from hydrodynamic full lubrication to the elastohydrodynamic area in bearings to the boundary friction conditions at TDC and BDC [203]. All friction pairings and a whole series of parameters are covered. The temperatures encountered range from ambient in the Arctic (− 40 °C) to sump temperatures of 100 °C to peak values of over 300 °C under the piston crown.

During the combustion process, the engine oil helps to seal the piston and cylinder. At the same time, it should burn off at the cylinder wall without leaving any residue. The engine oil dissipates heat from the piston and thus cools it. The blow-by gases formed when fuel is burned and their reaction byproducts have to be neutralized and held in suspension. The same applies to the soot and sludge particles formed by incomplete combustion. The oil also transports dirt and any abraded particles to the oil filter and ensures its filterability. In addition, any water formed during the combustion process should be emulsified and even when higher water concentrations are present and when the phases separate as temperature falls, the oil should protect against corrosion.

Engine oils should reduce friction and wear during extreme, low-temperature start-ups as well as when the lubricating film is subject to high temperature and pressure in bearings and around the piston rings. Whereas the oil should still flow well and be pumpable without aeration at low temperatures (down to − 40 °C) to avoid metal-to-metal contact during cold start-ups, the lubricating film must perform satisfactorily in bearings and hydraulic tappets [204]. At low temperatures, additives must not precipitate and the oil must not gel. At the upper end of the

temperature scale, the oil must offer far-reaching resistance to thermal and mechanical aging. And finally, the stability of the lubricating film should not be diminished by fuel dilution of up to 10 %.

The viscosity of an engine oil is an indicator of how readily a load-carrying film can be formed at all lubrication points in an engine. The adequate and rapid circulation of the oil at low temperatures [205] must be achieved at cold start cranking speeds. On the other hand, viscosity must not fall too much at high temperatures so that adequate lubricating film stability is given at high thermal loads.

Corresponding threshold values were determined by the SAE and the ASTM as shown in Table 8.

According to this list, all viscosity grades can be described by their minimum kinematic viscosity at 100 °C. Additional dynamic viscosity thresholds apply to winter grades, which display the letter W. These values are determined in cold cranking simulators (CCS) or in minirotary viscometers (MRV). The dynamic viscosity value given by the CCS is a measure of flow properties [206] at low temperatures whereby the high shearing rate can mask paraffin crystallization. In the MRV, a so-called threshold viscosity of max. 60 000 mPa · s has been determined for 10 °C lower temperatures to ensure that the oil pump does not draw air.

Figure 38. Comparison of monogrades and multigrades

The high-temperature high-shear viscosity is an additional criterion for evaluating lube film stability at high shear rates and high temperatures in summer grades. Modern engine oils are multigrade oils whose low temperature characteristics are indicated by the W and the high temperature viscosity by the number following the W. The $V-T$ behavior of multigrade oils is schematically sketched in Fig. 38.

8.1.1.2. Performance Specifications

The engine oil market is shifting away from conventional products to semisynthetic and synthetic formulations. Along with their higher price, the economic and ecological demands on these oil have also risen (see Chap. 4).

At present, the oil change intervals for cars are between 10 000 and 20 000 km and 30 000 and 60 000 km for trucks. In the future, these figures are expected to double. A retrospective view of specific oil performance shows that this development has been in progress for the last 50 years [207]. Figure 39 shows that oil consumption per energy unit has fallen eight times during this period.

As the established CEC engine tests do not allow comprehensive testing of all required oil properties, additionally in-house methods are now being used. A series of automobile manufacturer original manufacturer (OEM) specific, long-term trials, which have now been taken over for developing oils, are part of these engine tests. In total, these tests represent an enormous technical advance and financial expense because the engine tests themselves have been supplemented by radionuclide techniques [208]. The advantages of this technology lie in the on-line monitoring of wear in defined running conditions, from running-in to full-throttle operation as well as the selective examination of critical engine components.

8.1.1.3. Formulation of Engine Oils

Engine oils are complex mixtures of base oils and additives. Compared to other groups of lubricants, the base oils [209] play an important role (see Chaps. 4 and 5). Mixtures of base oils are selected which have the necessary viscosity and performance to correspond to a rough classification. The final products are then marketed as conventional, mineral oil-based, unconventional semisynthetic (hydrocracked) and synthetic engine oils. Precise international nomenclature divides base oils into five groups:

Table 8. Engine oil viscosity classification (SAE J 300 revised 4/1997).

SAE viscosity grade	Low temperature cranking viscosity (mPa · s) at temp. in °C (CCS)	Low temperature pumping viscosity (mPa · s) at temp. in °C (MRV)	Low shear-rate kinematic viscosity at 100 °C (mm^2/s)		High shear-rate viscosity at 150 °C and $10^6\ s^{-1}$ (mPa · s)
	Maximum	Maximum	Minimum	Maximum	Minimum
0 W	3250 at − 30	60 000 at − 40	3.8	–	–
5 W	3500 at − 25	60 000 at − 35	3.8	–	–
10 W	3500 at − 20	60 000 at − 30	4.1	–	–
15 W	3500 at − 15	60 000 at − 25	5.6	–	–
20 W	4500 at − 10	60 000 at − 20	5.6	–	–
25 W	6000 at − 5	60 000 at − 15	9.3	–	–
20	–	–	5.6	< 9.3	2.6
30	–	–	9.3	< 12.5	2.9
40	–	–	12.5	< 16.3	2.9*
40	–	–	12.5	< 16.3	3.7**
50	–	–	16.3	< 21.9	3.7
60	–	–	21.9	< 26.1	3.7

* For 0 W, 5 W, 10 W. ** For 15 W, 20 W, 25 W and Monogrades.

Figure 39. The history of oil stress

- Group 1: SN mineral oils with saturates < 80, 80 < VI < 120, S > 0.1
- Group 2: HC oils with saturates > 80, 80 < VI < 120, S < 0.1
- Group 3: HC oils with saturates > 80; VI > 120, S < 0.1
- Group 4: Polyalphaolefins
- Group 5: Esters and others

8.1.1.4. Additives

Depending on the base oil used and the required engine performance, engine oils can contain up to 30 different additives whose percentage content can range from 5 to 25 % in total. As a rule, performance additives make up the largest group.

Performance Additives. The following species of chemical components are summarised under the general term of performance additives (Table 9).

Table 9. Performance additives

Antioxidants	phenols and amines
Antiwear agents	metal dithiophosphates, carbamates
Detergents	Ca and Mg sulfonates, phenolates, salicylates
Dispersants	polyisobutene and ethylene-propene oligomers with nitrogen and/or oxygen containing functional groups
Friction modifiers	MoS compounds, alcohols, esters, fatty acid amides, etc.
Antimisting agents	silicones and acrylates

These additive groups are described in detail in Chapter 6. Particularly in the case of engine oils, the substance categories listed generally perform more than one function. ZnDTPs, for example, are primary antiwear additives but also have a secondary antioxidant character resulting from a specific decomposition mechanism [210]. Furthermore, complex formulations of a number of individual components typically display synergistic as well as antagonistic interactions which have to be matched to the application considered. The composition of the base oil components has an additional effect on these specific interactions. Considerable experience and know how is thus necessary to create an optimum formulation.

Viscosity Modifiers and Pour-Point Depressants (see Section 6.2). Viscosity modifiers can be divided into two groups, the nonpolar, nondispersing and the polar, dispersing group. The first group are only really needed to set the viscosity of multigrade oils. In an absolute concentration of 0.2 to 1.0 %, viscosity modifiers can generate a viscosity increase of between 50 and 200 % depending on chemical structure and base oil solubility. Due to special modification, dispersing viscosity improvers are often ashless dispersants with additional thickening effects. Furthermore, viscosity improvers and pour point depressants have an effect on low temperature behavior of a formulation (pour point, cold cranking simulator, mini rotary viscometer) and are essential parts of the high-temperature high-shear viscosity. In the USA, additional demands are made on low-temperature stability (gelation index) which cannot be achieved without the viscosity improvers and pour point depressants being matched to the base oil.

8.1.2. Characterization and Testing

8.1.2.1. Physical and Chemical Testing

The physicochemical properties of an engine oil can be determined in the laboratory with standard test methods (Section 16.3). This characterization mainly focuses on rheological test values and the previously shown SAE classification system.

Various viscosity tests are used to determine exact low- and high-temperature viscosities [211]. The viscosity thus determined is a characteristic of the engine oil at a defined engine state. At low temperatures (− 10 to − 40 °C), a mini rotary viscometer with a low shear gradient is used to determine the apparent viscosity and thus the oil's flowability in the area of the oil pump. In addition, maximum viscosity as the threshold of viscosity is determined in five graduated steps. The dynamic CCS viscosity, which is determined at − 5 to − 30 °C with a high shear gradient, is also an apparent viscosity which represents the tribological conditions at the crankshaft during cold starts. The maximum values laid down in SAE J 300 guarantee reliable oil circulation during the start-up phase. The rheological characteristics at higher thermal loads which occur during full-throttle operation are described by the dynamic viscosity at 150 °C and a shear rate of 10^{-6} s^{-1} or high-temperature high-shear (HTHS). The corresponding threshold values also guarantee an adequate lube film even in these conditions.

Apart from the rheological characteristics, the Noack evaporation test (see Section 16.3) is used to test the volatility of base oils and additives as well as foaming tendency and air release. The compatibility of high-additive oils with seal materials is tested on standard reference elastomers in static swelling and subsequent elongation tests [212]. The viscosity loss resulting from mechanical load is described in Section 6.2.

8.1.2.2. Engine Testing

Because realistic engine oil tests cannot be performed only over year-long field trials, a number of international committees have created methods of testing engine oils in defined test engines operated in reproducible and practically relevant conditions.

In Europe, the Coordinating European Council for the Development of Performance Tests for Lubricants and Fuels (CEC) is responsible for testing, approval and standardization [213]. Performance requirements are set-up in the form of Association des Constructeurs Europeen d'Automobiles (ACEA) limits which are decided together with the additive and lubricant industries. In the USA, this task is performed by

the automobile industry and the API. This institution lays down test procedures and limits. The Asian ILSAC has largely adopted the American specifications for automobiles.

In principle, the test procedures detailed in Section 8.1.3 focus on the following general performance criteria:

- oxidation [214] and thermal stability
- dispersion of soot and sludge particles
- protection against wear [215] and corrosion
- foaming and shear stability [216]

8.1.2.3. Passenger Car Engine Oils

Car engines include all gasoline and light diesel engines with direct or indirect injection. Relevant passenger car engine tests are listed in Table 10.

Table 10. Passenger car engine tests

Test engine	Test procedure	Test criteria
Peugeot XUD 11	CEC L-56-T-95	soot handling piston cleanliness
Peugeot TU3 H	CEC L-55-T-95	oxidation cleanliness ring sticking
Peugeot TU3 S	CEC L-38-A-94	cam and tappet wear
Sequence II D	ASTM STP B15 M P1	bearing corrosion
M 111 SL	CEC L-53-T-95	black sludge cam wear
Sequence IIIE	ASTM STR 315 M P2	oxidation wear cleanliness
Sequence VE		sludge piston cleanliness corrosion and wear
BMW M52		valve train air entrainment wear
VW T4		oil oxidation TBN depletion piston cleanliness
M111 FE	CEC L-54-T-96	fuel efficiency
VW-DI	P-VW 1452	piston cleanliness ring sticking
VW-TD	CEC L-46-T-93	piston cleanliness ring sticking

8.1.2.4. Engine Oil for Commercial Vehicles

Commercial vehicles include trucks, buses, tractors, harvesters, construction machines and stationary machinery powered by diesel engines. Apart from the prechamber diesels engines which have largely been superceded in Europe, the engines are usually highly turbocharged direct injection motors. Economic and ecological aspects along with high injection pressures, have improved combustion and thus reduce emissions. As an initiative of ACEA, oil change intervals have been extended up to 100 000 km for long haulage.

Long life and reliability are the criteria for the commercial vehicle sector. The HD oils have to match these requirements. Relevant heavy-duty engine tests are listed in Table 11.

Table 11. Heavy-duty engine tests.

Test engine	Test procedure	Test criteria
Caterpillar 1K/1N		piston cleanliness wear oil consumption
Cummins M11		valve train wear sludge
Mack T8		soot handling
Mack T9		cylinder wear
GM 6.2 Liter		valve train wear
OM 364LA	CEC L-42-T-99	piston cleanliness cylinder wear sludge oil consumption
OM 602A	CEC L-51-A-98	wear cleanliness oxidation oil consumption
OM 441LA	CEC L-52-T-97	piston cleanliness cylinder wear turbocharger deposits

HD oils are allocated to the following categories with increasing performance:

- heavy duty (HD)
- severe heavy duty (SHPD), and
- extreme heavy duty (XHD)

Independent of the viscosity grade and the base oils used, classic HD oils have a high reserve alkalinity and thus a higher content of alkaline-earth salts and organic acids [217]. Also regarding ashless dispersants, the oils are designed for at soot dispersing. Special viscosity improvers are used generally to avoid additional deposits.

Oils for vehicle fleets pose a particular challenge. As opposed to special products, these should simultaneously satisfy as many car and truck demands as possible. Possible piston cleanliness provided by high concentrations of

Table 12. Engine oil classification according to API SAE J 183

Gasoline engines	(Service classes)
API-SA	Regular engine oils possibly containing pour point improvers and/or foam inhibitors.
API-SB	Low-additive engine oils low-power gasoline engines. Include additives to combat aging, corrosion and wear. Issued in 1930.
API-SC	Engine oils for average operating conditions. Contain additives against coking, black sludge, aging, corrosion and wear. Fulfil the specifications issued by US automobile manufacturers for vehicles built between 1964 and 1967.
API-SD	Gasoline engine oils for more difficult operating conditions than API-SC. Fulfil the specifications issued by US automobile manufacturers for vehicles built between 1968 and 1971.
API-SE	Gasoline engine oils for very severe demands and highly-stressed operating conditions (stop and go traffic). Fulfil the specifications issued by US automobile manufacturers for vehicles built between 1971 and 1979. Covers API-SD; corresponds approximately to Ford M2C-9001-AA, GM 6136 M and MIL-L 46 152 A.
API-SF	Gasoline engine oils for very severe demands and highly-stressed operating conditions (stop and go traffic) and some trucks. Fulfil the specifications issued by US automobile manufacturers for vehicles built between 1980 and 1987. Surpasses API-SE with regard to oxidation stability, wear protection and sludge transportation. Corresponds to Ford SSM-2C-9011 A (M2C-153-B), GM 6048-M and MIL-L 46 152 B
API-SG	Engine oils for the severest of conditions. Include special oxidation stability and sludge formation tests. Fulfil the specifications issued by US automobile manufacturers for vehicles built between 1987 and 1993. Specifications similar to MIL-L 46 152 D
API-SH	Specification for engines oils built after 1993. API-SH must be tested according to the CMA's Code of Practice. API-SH largely corresponds to API-SG with additional demands regarding HTHS, evaporation losses (ASTM and Noack tests), filterability, foaming and flash point. Furthermore, API-SH corresponds to ILSAC GF-1 without the Fuel Economy test but with the difference that 15W-X multigrade oils are also permissible.
API-SJ	Supercedes API-SH. Greater demands regarding evaporation losses. Valid since 10/96.
Diesel engines	**(Commercial classes)**
API-CA	Engine oils for low-power gasoline and normally aspirated diesel engines run on low-sulfur fuels. Corresponds to MIL-L 2 104 A Suitable for engines built into the 1950s.
API-CB	Engine oils for low-to-medium power gasoline and normally aspirated diesel engines run on low-sulfur fuels. Corresponds to DEF 2101 D and MIL-L 2104 A Suppl. 1 (S1). Suitable for engines built from 1949 on. Offer protection against high-temperature deposits and bearing corrosion.
API-CC	Gasoline and diesel engine oils for average to difficult operating conditions. Corresponds to MIL-L 2 104 C Offer protection against black sludge, corrosion and high-temperature deposits. For engines built after 1961.
API-CD	Engine oils for heavy-duty, normally aspirated and turbocharged diesel engines. Covers MIL-L 45 199 B (S3) and corresponds to MIL-L 2 104 C Satisfies the requirements of Caterpillar Series 3.
API-CD II	Corresponds to API-CD. Additionally fulfils the requirements of US 2-stroke diesel engines. Increased protection against wear and deposits.
API-CE	Engine oils for heavy-duty and high-speed diesel engines with or without turbocharging subject to fluctuating loads. Greater protection against oil thickening and wear. Improved piston cleanliness. In addition to API-CD, Cummins NTC 400 and Mack EO-K/2 specifications must be fulfilled. For US engines built after 1983.
API-CF	Replaced API-CD for highly turbocharged diesel engines in 1994. High ash. Suitable for sulfur contents $> 0.5\,\%$.
API-CF-2	Only for 2-stroke diesel engines. Replaced API-CD II in 1994.
API-CF-4	Engine oil specification for high-speed, 4-stroke diesel engines since 1990. Meets the requirements of API-CE plus additional demands regarding oil consumption and piston cleanliness. Lower ash content.
API-CG-4	For heavy-duty truck engines. Complies with EPA's emission thresholds introduced in 1994. Replaced API-CF-4 in June 1994.
API-CH-4	Replaces API-CG-4. Suitable for sulfur contents $> 0.5\,\%$.
All engines	(Energy Conserving)
(API-EC I)	(min. 1.5 % less fuel consumption than an SAE 20W-30 reference oil in a 1982, 3.8 liter, Buick V6 gasoline engine. Sequence VI test)
(API-EC II)	Same as API-EC I but with minimum 2.7 % lower fuel consumption
API-EC	Replaces API-EC I and II. Only together with API-SJ. Cuts in fuel consumption: 0W-20, 5W-20 $> 1.4\,\%$, 0W-XX, 5W-XX $> 1.1\,\%$, 10W-XX, others $> 0.5\,\%$, Sequence VI A test: In a 1993, 4.6 liter Ford V8 engine. Reference oil 5W-30

over-based soaps is sacrificed because gasoline engines are prone to self-ignition if high proportions of metal detergents are present. As a result, other components are selected, such as the skillful use of unconventional base oils along with detergents, dispersants, *VI* improvers and antioxidants.

8.1.3. Classification by Specification

8.1.3.1. MIL Specifications

These specifications originate from the US Forces which set the minimum requirements for their engine oils. These are based on certain physical and chemical data along with some standardized engine tests. In the past, these classifications were also used in the civilian sector to define engine oil quality. In the 1980s, these specifications have become almost irrelevant for the West European market.

MIL-L-46152 A to MIL-L-46152 E. These military specifications have now been discarded. Engine oils which meet these specifications are suitable for use in US gasoline and diesel engines. MIL-L-46152 E (discarded in 1991) corresponds to API SG/CC.

MIL-L-2104 C classifies high-additive engine oils for US gasoline and normally aspirated and turbocharged diesel engines.

MIL-L-2104 D covers MIL-L-2104 C and requires an additional engine test in a highly-charged Detroit two-stroke diesel engine. In addition, Caterpillar TO-2 and Allison C-3 specifications are fulfilled.

MIL-L-2104 E similar in content to MIL-L-2 104 C The gasoline engine tests have been updated and include more stringent test procedures (Seq. III E / Seq. V E)

8.1.3.2. API and ILSAC Classification

The API together with the ASTM and the SAE have created a classification in which engine oils are classified according to the demands made on them, bearing in mind the varying conditions in which they are operated and the different engine designs in use (Table 12). The tests are standard engine tests. The API has defined a class for gasoline engines (S = service oils) and for diesel engines (C = commercial). Diesel engines in passenger cars are almost unheard of in the USA. In addition, a number of fuel economy stages has been determined (EC = energy conserving).

8.1.3.3. ACEA Specifications

As a result of persistent internal differences, the CCMC was disbanded and succeeded by the ACEA. CCMC specifications remained valid in the interim period. The new ACEA classifications (Table 13) came into force on January 1, 1996.

Table 13. Engine oil classification according to ACEA – Part I

Gasoline engines	
A1-96	Category for low-viscosity engine oils particularly low HTHS viscosity (< 3.5 mPa · s). This engine oil type was initially favored by Ford and Rover. Recommended viscosity grades are xW-30 and xW-20.
A2-96	Category for conventional and low-viscosity engine oils (no restriction on the permissible viscosity grades) with increased demands on the former CCMC G4. Out-performs API SH.
A3-96	Category for conventional and low-viscosity engine oils (no restriction on the permissible viscosity grades). Out-performs ACEA A2-96 with regard to Noack (evaporation losses), piston cleanliness and oxidation stability. Furthermore, out-performs API SH, CCMC G4 and G5.
Car diesel engines	(Light duty diesel engines)
B1-96	Category for low-viscosity engine oils with particularly low HTHS viscosity (corresponds to A1-96).
B2-96	Category for conventional and low-viscosity engine oils (no restriction on the permissible viscosity grades) with increased demands on the former CCMC PD 2.
B3-96	Category for conventional and low-viscosity engine oils (no restriction on the permissible viscosity grades). Out-performs ACEA B2-96 with regard to cam wear, piston cleanliness and viscosity stability in high soot conditions.
Truck diesel engines	(Heavy-duty diesel engines)
The new ACEA categories for truck diesel engines are largely based on Mercedes – Benz specification sheets.	
E1-96	Corresponds in general to the former CCMC D4.
E2-96	Largely based on Mercedes – Benz Sheet 228.1. Mack T8 test is also required.
E3-96	Largely based on Mercedes – Benz Sheet 228.3. Mack T8 test is also required.

The ACEA specifications were revised in 1996 and replaced by 1998 versions. Tests could be performed to 1996 specifications until March 1, 1999. The 1998 specifications became valid on March 1, 1998. 1996 specifications ceased to be valid on March 1, 2000. When ACEA specifications are quoted, the year must no longer be given.

Additional foaming tests were introduced for all categories and the elastomer tests were modified (Table 14).

Table 14. Engine oil classification according to ACEA – Part II

Gasoline engines	
A1-98	Category for Fuel Economy engine oils with especially low HTHS viscosity ($< 3.5\,\mathrm{mPa \cdot s}$). Recommended viscosity grades are xW-30 and xW-20. Compared to a 15W-40 reference oil, fuel savings of $\geq 2.5\,\%$ must be proven in a Mercedes test engine (M 111).
A2-98	Category for conventional and Fuel Economy engine oils. Replaces A2-96.
A3-98	Category for conventional and Fuel Economy engine oils with greater requirements than A2-98. Surpasses ACEA A2-98 with regard to Noack (evaporation losses), piston cleanliness and oxidation stability. Replaces A3-96.
Car diesel engines	(Light duty diesel engines)
B1-98	Category for Fuel Economy engine oils with especially low HTHS viscosity (same as A1-98). Recommended viscosity grades are xW-30 and xW-20. Compared to a 15W-40 reference oil, fuel savings of $\geq 2.5\,\%$ must be proven in a Mercedes test engine (M 111). Replaces B1-96.
B2-98	Category for conventional and Fuel Economy engine oils. Replaces B2-96.
B3-98	Category for conventional and Fuel Economy engine oils. Surpasses ACEA B2-98 with regard to cam wear, piston cleanliness and viscosity stability in high soot conditions. Replaces B3-96.
B4-98	New category for direct injection diesel engines (TDI).
Truck diesel engines	(Heavy-duty diesel engines)
E1-98	Corresponds to ACEA E1-96.
E2-98	Corresponds to ACEA E2-96.
E3-98	Corresponds to ACEA E3-96.
E4-98	Largely based on Mercedes – Benz Sheet 228.5. No OM 364 A engine test required but Mack T8 and T8E.
(E5xx)	(Planned category which should include all requirements which reduce wear caused by soot and deposits)

8.1.3.4. Manufacturers' Approvals

Apart from the specifications listed in Tables 13, 14, and 15, a number of manufacturers demand tests on their own engines (Table 15).

8.1.3.5. Future Trends

New generations of engines using optimized technologies advance the concept of tailor-made, special oils.

The continuing optimization of the combustion process to increase the efficiency of gasoline engines has led to the development of direct-injection gasoline engines (GDI engines) which may offer fuel savings of about 20 %. On the diesel side, direct injection with unit pumps or common rail technology using pressure of up to 3000 bar have become the norm. These designs which originate in truck engines, offer power increases of up to 50 % at almost constant fuel consumption. In the truck area, reducing exhaust emissions has the highest priority. The present thresholds of Euro 2 and Euro 3 (from 2001) will be easily surpassed with special exhaust recycling and catalytic converter systems. As these generations of engines will require low-sulfur diesel fuels (10 ppm), new demands will be made on the lubricants used.

Furthermore, the surface treatment of pistons and cylinders has improved to such an extent that topology-specific oil consumption is steadily falling. In addition, oil change intervals have been constantly increased. All in all, three factors will characterize engine oils of the future – fuel efficiency, long oil drain intervals, and low emissions.

Fuel Efficiency. As a result of strict limits to fuel consumption in the USA (CAFE = Californian Act for Fuel Emissions) and the proven fuel economy effect of low-viscosity engine oils [218], this topic is attracting attention in Europe and Asia. As a rule, engine-based savings can reach a theoretical $8 - 10\,\%$ [219]. As engine oils cannot totally eliminate frictional losses, saving potentials of 4 and 5 % present enormous challenges. However, values of between 3 and 4 % are already possible today.

Table 15. Manufacturers' approvals

VW-Norm	Application area
VW 50000	Low-viscosity oils for gasoline and normally-aspirated diesel engines. Only SAE 0W-XX, 5W-XX and SAE 10W-XX oils. XX $>$ 40 oils were not included after 10/91.
VW 50101	Multigrade engine oils without low-viscosity characteristics for gasoline and normally-aspirated diesel engines.
VW 50200	New specification for car gasoline engines with extended oil change intervals.
VW 50300	New specification for car gasoline engines with extended service intervals. Surpasses the requirements of 50200 (HTHS $\geq$ 2.9 mPa · s).
VW 50301	Planned specification for turbocharged car gasoline engines with extended service intervals (HTHS $>$ 3.5 mPa · s).
VW 50500	All-season engine oils for diesel engines with or without turbocharging.
VW 50501	All-season engine oils especially for Unit Pump diesel engines.
VW 50600	New specification for diesel engines with extended service intervals (HTHS $\geq$ 2.9 mPa · s).
VW 50601	Planned specification for Unit Pump diesel engines with extended service intervals.
MB Sheet	**Application area**
MB 226.0	Monograde engine oils for normally-aspirated diesel engines.
MB 227.0	Monograde engine oils for turbocharged diesel engines.
MB 227.1	Multigrade engine oils for turbocharged diesel engines.
MB 228.1	Multigrade engine oils for turbocharged diesel engines. Oil change intervals up to 30 000 km.
MB 228.3	SHPD engine oils for highly turbocharged diesel engines. Extended oil change intervals up to 45 000 km.
MB 228.5	UHPD (ultra high performance diesel) engine oils for highly turbocharged diesel engines. Extended oil change intervals in light-duty engines up to 45 000 km. Up to 160 000 km possible in heavy-duty diesel engines (with service interval displays).
MB 229.1	Engine oils for cars (gasoline and diesel engines). Introduced 05/97. More stringent than ACEA A2-96/A3-96 and B2-96/B3-96.
MB 229.3	Engine oils for cars with extended oil change intervals (30 000 km).
MAN in-house specification	**Application area**
MAN 270	Monograde engine oil turbocharged and non-turbocharged diesel engines.
MAN 271	Multigrade engine oil turbocharged and non-turbocharged diesel engines.
MAN QC13-017/M 3275	SHPD engine oils for all diesel engines with oil change intervals up to 45 000 km.
MAN M3277	UHPD engine oils for all diesel engines with oil change intervals up to 80 000 km.
MAN 3271	Oil for engines run on gas (natural gas, propane or butane).
Scania	**Application area**
ACEA E3	Oil change intervals up to 60 000 km.
LDF approval	ACEA E3 oil with special long drain field-test approval. Oil change intervals up to 120 000 km.
VDS	Volvo drain specification for extended oil change intervals (50 000 km).
VDS-2	Specified for Euro 2 engines (60 000 km).
(ACEAE4-98)	DAF recommends oils with the following viscosities; 10W-40, 10W-30 and 5W-40. Oil change intervals up to 100 000 km.
Oil Type 1	Normal quality (ACEA E1-96, E2-96)
Oil Type 1∗	Type 1 plus corrosion protection
Oil Type 2	Higher quality (SHPD, ACEA E3-96)

Reduction in car fuel consumption in urban conditions are achieved by lowering frictional losses during cold start-ups which simultaneously result in less wear and a lowering of viscosity in constant throttle conditions. There is a plateau-like optimum for the correlative fuel savings in engines with HTHS values between 2.5 and 2.9 mPa · s.

According to OEMs, HTHS values must not be lower than minimum 2.6 mPa · s in all manufacturer's approvals and new engine oil developments because of possible wear between critical material pairings.

Long Drain Intervals. Concerns about higher wear and thus shorter life caused by low-

viscosity oils run contrary to the trends of the new generation of engines which are designed to cope with even longer oil change intervals. As stated in manufacturer's specifications, oil change intervals for cars are currently 15 000 km for gasoline engines and 30 000 km for diesel engines. At present there are demands to double these figures without detracting from the fuel efficiency and wear performance of the oil. As a result of these diverging requirements, future engine oil specifications might contain a whole series of new OEM-specific engine tests.

The radionuclide technique, as a proven on-line tool, is experiencing a renaissance for examining the effects on wear in various operating conditions such as during running-in or to determine long-term stability.

Apart from long-term wear, very high demands are made on high oxidation stability and low evaporation losses. This strengthens the trend towards synthetic and unconventional oil as the basis for such high performance engine oils. A graphic correlation between evaporation tendency (Noack) and oil consumption is given in Figure 40. A technically realized milestone for fully synthetic engine oils based on present synthetic base oils is an evaporation loss of 5 to 6 %.

The suitability of extended oil change interval oils is tested in thermally stressed test engines which run hot and without oil top-up. The typical indicators of aging like viscosity and TBN are measured.

Low Emission. Heavy-duty engine oils already achieve drain intervals of 100 000 km. Because of the ever increasing number of trucks on roads, this is a useful contribution to improving environmental compatibility.

Apart from the CO, HC and SO_2 emissions which are seen to be caused by the fuel, particulate emissions play a significant role in HD engines. These particulates are a result of incomplete combustion and are a mixture of fuel- and lubricant-based components. As the oil-based particles are largely caused by highly volatile elements in the formulation, evaporation losses have a direct effect on reducing pollutants (see Fig. 40). Furthermore, it is assumed that sulfur compounds in diesel fuels will poison the catalytic converters of future Euro 3 and Euro 4 engines. The call for low sulfur (10 ppm) and most probably low phosphorus engine oils will not only lead to a different assessment of additives but also to the rejection of solvent neutral oils which, as a rule, contain between 0.2 and 1.0 % sulfur. Similar to passenger cars unconventional and synthetic base oils are preferred so that the trend towards low viscosity, fuel economy oils will spread definitively to the heavy-duty sector.

8.2. Two-Stroke Oils

8.2.1. Application and Characteristics [220–222]

Two-stroke engines are mostly used when high specific power, low weight and low price are key parameters. These engines are thus often used in motorcycles, boats (outboard engines), jet-skis, lawn mowers, chain saws and small vans, whereby the vast majority are found in motorcycles and boats.

Almost all two-stroke engines use total-loss lubrication, i.e., the oil is not circulated as in the case of four-stroke engines but added to the fuel. A large part is burnt in the combustion process, about one quarter is exhausted as unburnt oil mist. Simple engines as found in older mopeds still use the premix method, whrere a suitable two-stroke oil to is added manually the fuel tank at a ratio of about 1 : 20 to 1 : 100. More advanced designs use an automatic oil metering system. These either add a constant amount of oil to the fuel or add oil according to engine loading. Typical oil : fuel ratios are between 1 : 50 and 1 : 400.

In the majority of simple two-stroke, the engine breathes through classic carburetors. Contrary to four-stroke engines, the fresh fuel/air mixture in a two-stroke engine scavenges the cylinder after combustion. This simultaneous charging and emptying causes about 30 % of the fresh mixture to be exhausted without burning.

This disadvantage, along with the only partial burning of the oil, causes many two-stroke engines to generate comparatively high emissions. In highly populated areas with a large number of small motorcycles, such as in many Asian cities, this leads to severe odor, smoke and noise pollution.

In recent years, these typical disadvantages have been countered by some advances in two-

Figure 40. Oil consumption and relative oil generated particulate emissions versus evaporation loss

stroke technology. The development of direct or indirect fuel injection has led to significantly reduced emissions and improved fuel efficiency.

Today's engines require correspondingly high quality oils for reliable operation and long life. The principal criteria for the quality of two-stroke oils are:

- lubricity and antiwear properties
- cleaning function (detergent/dispersant properties)
- avoidance of deposits in the exhaust system
- low smoke
- spark plug cleanliness and the avoidance of preignition
- good fuel miscibility even at low temperatures
- corrosion protection
- good flowing properties

About 85 – 98 % of two-stroke oils are base oils with the rest consisting of various additives. In principle, all common base oils can be used, ranging from brightstocks, solvent neutral types to fully synthetic polyalphaolefins. Higher quality two-stroke lubricants often contain various synthetic esters and this is particularly the case for biodegradable oils which were specially developed for marine outboards.

The additives in two-stroke oils are usually matched to the requirements of the engine. As in the case of four-stroke engine oils, antiwear additives are included in two-stroke oils. Along with the most commonly used zinc dialkyldithiophosphates, nonash-forming types such as dithiophosphoric acid esters of alkyl and aryl esters or phosphoric acids are used.

The following DD additives are added to the oil: Alkali or alkaline-earth salts of sulfonates and/or phenolic compounds, and polybutene succinimides.

Furthermore, two-stroke oils contain small quantities of antioxidants, corrosion inhibitors, defoamers and flow improvers in addition to antiwear and DD additives.

Low-smoke two-stroke oils contain a significant amount of fully synthetic fluids, i.e., polybutenes (about 10 to 50 %). Apart from good lubricity compared to mineral oils, these fluids offer much cleaner combustion and significantly less coking [223], [224].

8.2.2. Classification

The basis for all classification systems are a series of laboratory and functional tests, the latter being bench tests performed on the latest generation of two-stroke engines.

8.2.2.1. API Service Groups

The API currently lists three categories (Table 16) which cover all engines from low-power

Table 16. API groups

API	Application	Test engine	Test criteria
TA	mopeds, lawn mowers, electricity generators, pumps	Yamaha CE 50 S (50 cm^3)	piston seizing, exhaust system deposits
TB	scooters, small motorcycles	Vespa 125 TS (125 cm^3)	preignition, power loss due to combustion chamber deposits
TC	high-performance motorcycles, chain saws	Yamaha Y 350 M2 (350 cm^3) Yamaha CE 50 S	preignition, power loss due to combustion chamber deposits piston seizing, ring sticking

lawn mowers to high-performance motorcycles. Engine tests are no longer performed because the specified test engines are no longer manufactured. In future, it is planned to replace the API groups with Japanese JASO and global ISO classifications. There are still a number of oils on the market with API classifications because this system was widely accepted in the past.

8.2.2.2. JASO Classification

Japanese Automotive Standards Organization (JASO), to which all major Japanese vehicle manufacturers belong, classifies two-stroke oils into three groups, FA, FB and FC (Table 17).

Table 17. JASO performance categories (Reference oil: JATRE 1 = 100)

Test criteria	JASO FA	JASO FB	JASO FC
Lubricity	> 90	> 95	> 95
Detergent effect	> 80	> 85	> 95
Exhaust smoke	> 40	> 45	> 85
Exhaust deposits	> 30	> 45	> 90

Table 18. Engine test criteria for JASO classifications

Test engine	Test criteria	Test parameters
Honda Dio AF 27	lubricity	piston ring wear, ring scuffing, piston seizing
Honda Dio AF 27	detergent effect	piston ring sticking as a result of lacquering, coking, deposits on piston and in combustion chamber
Suzuki SX 800 R	exhaust smoke	smoke particles
Suzuki SX 800 R	exhaust deposits	back pressure in exhaust system

All three categories use the same test engines and the corresponding performance category is allocated according to predetermined thresholds. The test results are determined in comparison to an exactly defined, high-performance reference oil (JATRE 1) and published as an Index relative to JATRE 1 (Table 18). The key test criteria are the lubricity and detergent effect of the oil as well as its tendency to create smoke and deposits in the exhaust system. The first specification for a low-smoke oil was created with the laying-down of JASO FC.

8.2.2.3. ISO Classification

In the mid-1990s, after JATRE 1 oils were tested in European engine tests, it became clear that JASO FC oils could no longer satisfy the latest demands of European two-stroke engines. An series of extended tests which satisfied all demands were thus developed in Europe. In addition to the testing of smoke, exhaust system deposits, lubricity and detergent effect according to JASO, a new category with a 3-h Honda Dio test to quantify improved piston cleanliness and detergent effect was added. The reference oil for all tests was JATRE 1. These new guidelines were created by CEC working parties in which European engine and lubricant manufacturers are represented.

The ISO now classifies two-stroke oils into three categories, ISO-L-EGB, -EGC and -EGD. A fourth category (-EGE) is currently being drafted with strong European representation.

The categories ISO-L-EGB and -EGC mirror the requirements of the JASO categories FB and FC while requiring additional proof of piston cleanliness. ISO-L-EGC and -EGD require proof of low smoke similarly to JASO FC. Table 19 shows all engine-based evaluation criteria.

Table 19. Summary of the ISO categories (Reference oil: JATRE 1 = 100)

Test criteria	ISO-L-EGB (incl. JASO FB)	ISO-L-EGC (incl. JASO FC)	ISO-L-EGD
Lubricity	> 95	> 95	> 95
Smoke	> 45	> 85	> 85
Exhaust deposits	> 45	> 90	> 90
Detergent effect	> 85 (1-h test)	> 95 (1-h test)	> 125 (3-h test)∗
Piston cleanliness	> 85 (1-h test)∗	> 90 (1-h test)∗	> 95 (3-h test)∗

∗ New requirements in addition to JASO FC.

8.2.3. Oils for Two-Stroke Outboard Engines

Neither API nor JASO or ISO classifications contain quality guidelines for outboard engine oils. These are usually oils whose formulation and characteristics have been matched to the engine technologies which have become established for powering boats. The main difference to other two-stroke oils lies in their additive chemistry. The additives in these oils are all nonash-forming because these engines all display a marked coking tendency in certain parts of the combustion chamber, such as the ring grooves. The performance categories of two-stroke oils for outboard engines were primarily developed by the American National Marine Manufacturers Association (NMMA). Back in 1975, the minimum requirements of such oils were incorporated into the TCW specification. In 1988, a far-reaching revision was issued with the title TCW 2. During the following years, problems were encountered with technologically advanced engines which were run on TCW or TCW 2 oils. This initiated a further tightening-up of minimum requirements, which was released as TCW 3. In 1997, the standards for oil quality were again increased to keep pace with continuing developments in engine technology. The new specification, TCW 3-R (R = recertified), now includes laboratory tests and tests on five different engines, three of which are outboards. Table 20 shows the tests which have to be performed on a newly developed outboard engine oil to achieve TCW 3-R classification. The costs generated by testing a TCW 3-R product development have never been so high. The engine tests alone generate costs of about $ 150 000 – 200 000.

Table 20. Test criteria for NMMA TCW 3-R

Engine Tests	
Test engine:	Test criteria:
Yamaha CE 50 S	lubricity (seizures)
Yamaha CE 50 S	power loss due to preignition
Mercury 15 HP (2 runs)	compression losses, ring jamming, piston cleanliness
OMC 40 HP	ring jamming, piston cleanliness
OMC 70 HP	ring jamming, piston cleanliness
Laboratory Tests	
Low-temperature viscosity	limited viscosity at −25 °C
Miscibility	mixing with fuel at −25 °C
Corrosion protection	standard rust tests compared to reference oil
Compatibility	stability after mixing with reference oil
Filterability	flow rate compared to pure fuel

8.2.4. Environmentally Friendly Two-Stroke Oils [225]

The ever increasing severity of environmental legislation is also effecting the development of two-stroke oils, especially outboard engine oils. Such ecologically optimized oils often have regionally differing classifications which reflect local environmental legislation and their biodegradability depends on varying minimum requirements. At the international level, the International Council of Marine Industry Associations (ICOMIA) has specified harmonized requirements [223]. In 1997, the ICOMIA Standard 27-97 was passed for environmentally friendly outboard engine oils. From a technical point of view, products thus labeled must fulfil at least TCW 3-R as well as offering very low algae, daphnia and fish toxicity and rapid biodegradability as defined by ISO and OECD standards. These oils are based on fully synthetic components with the base oils usually be-

ing rapidly biodegradable synthetic esters. By using correspondingly high quality esters, these products are the very best two-stroke oils and can even used for lubricating chain saws. The use of ester-based lubricants combines the highest technical performance with improved environmental compatibility.

8.3. Tractor Oils

Relatively newer generations of construction and agricultural machinery make differing demands on functional fluids. For reasons of simplified servicing but also because of the general wish to rationalize stocks, universal oils were developed which satisfy the various functional requirements of such machines.

These oils should guarantee long machinery life in all climatic conditions as well as extending service intervals and reducing down-time.

These days, two different oil technologies are used which are characterized by their application area. They are universal tractor transmission oils (UTTO) and super tractor oils universal (STOU).

The demands made on tractor oils have increased sharply in line with advances in vehicle technology and ease of operation.

Technical advances in tractors required a significant improvement in operating fluids as they did in the whole automotive area. Apart from big improvements in additive technology to cope with greater mechanical demands, the aging stability of the fluids has increased reflecting dramatically higher specific power outputs and lower oil volumes.

All-season use is now a standard requirement for tractor oils as it is in the automotive area. The result of this is that the viscosity grades and thus temperature ranges have been extended from SAE 15W-30 and 10W-30 to 15W-40, 10W-40 and 5W-40.

The performance of such universal oils as hydraulic fluids corresponds to, at least, HLP and HVLP levels because of the additives included to guarantee universal use.

The use of these products in vehicle gearboxes and wet brakes makes much greater demands on the fluid. Highly-stressed mechanical drive units make great demands on the wear protection and life of the lubricant. A special challenge to oil formulations is the use of these products in wet brakes which began back in the 1960s. Not least because of safety considerations, such oils must offer high thermal stability and balanced and stable friction characteristics in brakes. Fine-tuning these oils with special friction modifiers is one of the most difficult aspects of developing such oils.

While UTTO oils can satisfy the above-listed applications, their use as engine oils require vastly different additive packages. Apart from additives for friction and wear control, low-temperature stabilizers, oxidation, corrosion and foam inhibitors, engine oils additionally require significant quantities of detergents and dispersants. As a rule, normally aspirated engines require, at least, an API CE oil and if a turbocharger is fitted, the oil should be API CF or CF-4. In many cases, tractor engine manufacturers issue approvals for oils after they have successfully completed tests in the corresponding engines.

The latest generation of tractor oils not only include products with significantly higher performance than in the past but also oils which offer better environmental compatibility. Such products often contain rapeseed or sunflower base oils or synthetic, rapidly biodegradable esters.

Tractor manufacturers now issue their own, in-house fluid specifications which satisfy all specific requirements of the corresponding machinery. Table 21 lists several manufacturer specifications.

Table 21. Manufacturer specifications for tractor oils

Manufacturer	Oil type	Specification
Ford	STOU	ESN-M2C-159-C
Ford	UTTO	ESN-M2C-86-C
John Deere	STOU	JDM J 27
John Deere	UTTO	J 20 C, J 20 D
Massey Ferguson	STOU	CMS M1139, CMS M1144
Massey Ferguson	UTTO	CMS M1135, CMS M1143

8.4. Gas Engine Oils [226–228]

Gas has long been used to power vehicles and stationary engines. Such engines require a variety of lubricating oils, depending on the type of engine and the operating conditions.

There is currently no universal, harmonized specification for gas engine oils. The large variations in operating conditions between mobile and stationary engines generally require oils with different additive packages. A general differentiation is made between high-, medium-, and low-ash types which are recommended by the manufacturers in line with the designed use of the engine. As a rule, gas engine oils are subject to oxidation and nitration conditions which can accelerate the aging of the oil. Gas-powered cars normally use the same conventional engine oils as are used in gasoline-powered engines. Diesel engines usually need oils with a higher total base number and with more dispersants than gasoline engine oils. Typical qualities for car engines are API SH and/or ACEA A3 (gasoline engines) as well as API CG-4 and/or ACEA B3 (diesel engines). Similarly to the automotive sector, multigrade oils are used to cope with variable operating conditions and to guarantee reliable lubrication at low ambient temperatures. As the number of compressed natural gas (CNG) powered cars increases, there is increasing pressure to develop oils which are especially formulated for these applications. This could mark the beginning of a future, uniform specification.

Special multigrade oils have already been developed for use in heavy diesel engines, with CNG-powered buses being the major application. These have been tested and approved by various engine manufacturers. Examples of these approvals are Mercedes – Benz Sheet 226.9 or MAN M 3271. These oils were tested in bench tests as well as in realistic field trials.

Stationary gas engines can make significantly more complex demands on the oil and this has an effect on their development. While the common ACEA or API bench tests suffice for CNG-powered car engines, laboratory tests on gas engine oils are limited to initial oil screening. The real development takes place in field trials in which engines often have to run for years before they are evaluated. While particular attention is paid to sludge formation, valve train wear and low temperature flowing in car engines, other effects are important in stationary engines. Particularly important is controlling oil aging caused by oxidation and nitration but also preignition which is caused by high levels of ash-forming additives. This problem is most prevalent in two-stroke engines which generally need low-ash oils. Simply because of their long service lives, gas engine oils should protect against valve seat recession and spark plug fouling. As regards running on corrosive gases (caused by sulfur or halogen contamination), special attention must be paid to adequate corrosion protection. The development and application of gas engine oils normally takes place in close cooperation between the oil and engine manufacturers.

8.5. Marine Diesel Engine Oils [229]

These lubricants are heavily influenced by the type of fuel used and the design of the engines themselves. A number of similar engines are also used in stationary applications to generate electricity with conventional fuels or with steam power.

8.5.1. Low-Speed Crosshead Engines

Low speed diesel engines generating up to 1000 kW per cylinder at 50 to 120 rpm use the crosshead principle (large engines with over 900 mm bores and 3000 mm strokes and 20 000 kW outputs). In crosshead designs, the cylinder block and the crankcase are separate units. Sealing is provided by stuffing boxes and the liners are lubricated with cylinder oils by means of dosing devices. Depending on the bore and stroke of the cylinder, up to 16 dosing devices may be fitted.

8.5.2. Medium-Speed Engines

Medium-speed engines run at around 200 to 100 rpm. The overall design of these engines is roughly similar to that of vehicle internal combustion engines, they do not use the crosshead design and the crankshaft is connected to the pistons and thus the cylinders with connecting rods. In such designs, the same oil is used to lubricate the cylinder walls and the crankshaft bearings and forms part of a circulation system. These engines are sometimes called trunk piston engines.

These days, marine diesel engines are fuelled by the worst and heaviest crude oil fuel cuts.

These include vacuum residues, propane deasphalting residues, heavy solvent extracts from lube refining and other byproducts (→ Heating Oils, Chap. 2.).

8.5.3. Lubricants

Cylinder oils in crosshead engines are total-loss products which lubricate the sliding motion of the piston rings in the cylinder liner. To avoid the deposit of combustion residues, these oils must have good dispersant properties. In addition, they must be capable of neutralizing the corrosive acids which result from the high sulfur levels in the fuels. To satisfy these requirements, cylinder oils have a large proportion of over-based components (up to 30 % over-based calcium sulfonates or other over-based components). The alkalinity required for neutralization leads to TBNs of up to 100. When additives for such oils are being selected, special attention must be given to the good colloidal solubility of the additives in the base oil to avoid precipitation. The large surface areas of cylinders in crosshead engines requires the applied oil to disperse rapidly and reliably and this is achieved by good spreadability.

The stuffing boxes fitted to crosshead engines ensure that the *crankcase oils* are hardly contaminated by combustion chamber residues and these oils thus contain relatively few additives. Additives to combat thermal oxidation are essential and the neutralizing capacity can be relatively low with a TBN of 5. The contamination of crankcase oil with cylinder oil leads to increased emulsifying capacity which is undesirable. Water separation is therefore another vital characteristic of crankcase oils.

An increase in dispersant and detergent properties caused by the ingress of cylinder oil can also lead to wear problems as the effect of typical antiwear and EP additives such as zinc dialkyldithiophosphate is thereby diminished.

The type of oil used to lubricate *trunk piston engines* (combined crankcase and piston lubrication) is also largely determined by the sulfur content of the fuel. Oils with TBNs of 12 to 40 are common and the neutralizing capacity of the oils is very soon exhausted in some cases so that the TBN of used oils can be much lower.

During the development of such oils, tests are performed on one- or three-cylinder Bolnes engines but final results are only available from very time-consuming on-board trials lasting at least one year.

Significant restrictions on the sulfur content of marine diesel fuels will be imposed in the coming years. This will result in a lowering of the high proportion of over-based components necessary for such oils at present.

9. Gear Lubrication Oils

9.1. Introduction

Gear lubrication oils are of particular significance for the transmission. Apart from the important function of lubricating the sliding rolling contacts, the oils also fulfil the task of cooling and removing the friction heat generated in the sliding rolling contacts.

In general, the lubricant is a transmission component which can be relatively simply produced at low cost. However, in order to ensure the reliable and long-term operation of a transmission, the selection of the lubricant, in comparison to the selection of the other machine components, is of decisive significance during the transmission construction.

The following base oils are not only used for the lubrication of transmissions but also many other applications:

- mineral oils
- synthetic hydrocarbons (polyalphaolefins)
- poly(alkylene glycols) (homopolymers)
- esters (eco-friendly oils, mainly on synthetic basis)
- rapeseed oil, castor oil

Apart from the various base oils, the type and quantity of the additive has a significant influence on the function and service life of a transmission.

In principle, any type of lubricant, including engine oils, can be used in any transmission, thus ensuring for the moment the transmission's functionality.

However, the selection of a lubricant which is not adapted to the respective construction components and the operating and environmental conditions of a transmission can, given an

early failure of the transmission, lead to maximum consecutive damages up to the breakdown of complete systems. The resulting repair and standstill times of the system lead to unforeseen costs.

9.2. Requirements of Gear Lubrication Oils

In many areas of machine construction, the transmission plays an important role. Figs. 41 and 42 give a general survey over the various transmission types used today.

Each of these transmission types makes specific requirements on the lubricant which must be met to ensure the reliable function of the machines and plants. Thus, the heavily loaded lubricants in hypoid gears require high oxidation stability, together with a very good scuffing and scoring and wear load capacity, due to the high load of the tooth contacts. At the same time, the formation of a load-capable and separating lubricating film for sufficient lubrication and cooling of the sliding rolling contacts in hypoid gears requires a lubricant with an adequately high viscosity at operating temperature.

On the other hand, lubricants used in hydrodynamic gears, such as torque converters, hydrodynamic clutch couplings or retarders, do not need to have a good scuffing and scoring load capacity. However, they must have a high oxidation stability. Due to the viscosity-dependent losses, lubricants which are used in hydrodynamic gears therefore have a clearly lower viscosity at operating temperature in comparison to lubricants used in hypoid gears.

The abovementioned transmission types are used in machine and plant construction with varying degrees of frequency. Figure 43 presents the service lives currently required of transmissions according to the most important industries in the area of machine construction.

The heat development in a transmission has an influence on the temperature of the oil sump and the temperature in the oil tank. Heat accelerates the oil's aging process and, therefore, can cause a reduction of the oil's service life. The heat development and, thus, the oil temperature, is determined by the transmission type, the transferred power, the specific load, as well as by the switching periods – permanent or intermittent operation – and by the environmental conditions – use of the transmission in warm or cold climates, or in a mobile or stationary system.

In transmissions for which long service lives are required, such as paper machines or presses, the lubricant has to be changed according to the mechanical and thermal claim, in compliance with the oil producers' recommendations. Assuming that the average oil sump temperature in such transmissions is approx. 90 °C, the oil should be changed in intervals of 2500 operating hours. An increase of the oil sump temperature of 10 K leads to a 50 % reduction of the service life, reducing the temperature by the same value doubles the oil's service life.

Today, transmissions for which short or medium service lives are required, as for example in passenger cars or mobile hydraulic systems, are mainly filled with life-time oil fillings. The oil sump temperatures in these transmissions often rise up to 130 °C. Therefore, the use of synthetic lubricants is recommended in these applications. In general, the service life of synthetic lubricants is three times longer than the service life of mineral oils. However, the current prices for synthetic lubricants are also three times higher than those for mineral oils.

9.3. Tribology of Gears

There are significant differences between the tribology of gear drives [230] and the tribology of journal and roller bearings, since the lubrication conditions characterizing the sliding rolling contacts in toothed wheels differ from those in journal or roller bearings. As shown in Figure 44, the lubrication conditions in the tooth contacts are the most difficult.

9.3.1. Friction Conditions of Gear Types

Figure 45 gives a schematic overview of the gear types currently used [231], [232].

According to its specifically different geometric ratios and the operating conditions, each gear type is limited to a maximum transferable load.

The main key factors are the sliding rolling contact pressure and the specific load in the tooth contact and the gear's rotational speed, as well as

Figure 41. Gears with a constant gear ratio

Figure 42. Gears with a variable gear ratio

Figure 43. Guide values for the service lives required of gears

the currently effective rolling and sliding speed proportions in the tooth contact. The distribution of these factors during a tooth engagement is shown in Figure 46 on a nonprofile corrected spur gear.

The load and surface velocity of the tooth flanks are characterized by continuously changing conditions alongside the entire tooth engagement distance. The sum of the velocity of the tooth flank equals the effective hydrodynamic velocity, v_Σ. The difference of the velocity of the tooth flank equals the sliding velocity v_g. Together with the locally effective pressure or so-called sliding rolling contact pressure, this sliding speed causes a friction load flowing tangentially to the tooth flank and, thus, an increase in temperature in the sliding rolling contact. Only in the pitch point contact C, as shown in Fig-

Figure 44. Schematic overview of the narrowing of the gap. (A) hydrodynamic journal bearings, constant sliding speed at good conformity and good lubrication conditions. (B) Cylindrical roller bearing, relatively high rolling speed at low sliding speed, poor conformity and medium lubrication conditions. (C) Tooth contact lubrication, poor conformity along the tooth engagement length at different sliding velocities in tooth-tip direction and under lubrication conditions inferior to A and B.

ure 46, a pure rolling movement can be observed without sliding speed in the whole tooth engagement.

For the toothing shown in Figure 46, a static load distribution alongside the tooth engagement distance can be assumed.

The tooth engagement is a vibrating system which, according to the geometry and the operational area, shows a dynamic load distribution which differs and sometimes clearly exceeds the static load distribution. In this vibrating system, the lubricant and, especially its operational viscosity have an absorbing effect.

Lubrication Film Generation in Tooth Contact. A significant key factor for the assessment of the lubrication generation and condition is the minimum lubricant film thickness. A sufficient minimum lubricant film thickness is necessary to avoid the metal surface contact of the tooth flanks and to lead the generated heat out of the contact zone by means of friction and absorption. With the minimum lubricant film thickness determined according to [234], [235], the current lubrication condition in the tooth contact can be assessed. The non-stationary sliding rolling contact conditions are the reasons for the differences in the lubrication conditions in each contact point of the tooth engagement distance.

In the pitch point C of a tooth engagement where – as in a roller bearing – a pure roll-off or rolling movement without slide speed proportions is generated, relatively optimal lubrication conditions can be assessed. The lubrication conditions during the tooth engagement and disengagement, however, are more unfavorable due to relatively high slide speed proportions.

Another factor with negative impact on the generation of a lubrication film in a tooth contact becomes effective during a new tooth engagement of each tooth when stripping off of the lubrication film by the tooth tip of the engaging toothed wheel. The lubrication film must be regenerated on this tooth tip with each new tooth engagement and breaks with each tooth disengagement.

When a gear is characterized by a more lubrication-unfavorable toothing geometry due to the relatively large slide – speed proportions along the tooth engagement length in this type of gear, for example in a hypoid or cylindrical worm gear, these gears are subject to significantly larger friction losses and higher sliding rolling contact temperatures than a simple spur gear.

Lubrication Conditions. To avoid tooth damage, a detailed observation and assessment of the lubrication conditions in the tooth contacts is particularly important.

Depending on the local load, pressure, temperature and based on the material values of the toothed wheels and the lubrication values of the lubricant, a lubricant film thickness flow over the tooth engagement distance of a toothing can be calculated [236]. Today, this method is generally used to calculate the pitch point C. Due to the fast progress made, a more complex observation of the tooth engagement is only a matter of time and is already partly carried out as a standard method by some companies.

The specific film thickness of the lubricant film is assessed according to the Eq. (10.1):

$$\lambda = h_{\min}/R_{\mathrm{a}} = 2h_{\min}/\left(R_{\mathrm{a1}} + R_{\mathrm{a2}}\right) \tag{10.1}$$

Figure 45. Important gear types

where λ is the specific film thickness according to [237], $h_{\min}$ is the minimum film thickness according to [233], and R_{a} is the arithmetic average mean roughness of the tooth flanks of pinion (R_{a1}) and wheel (R_{a2}) according to [238].

According to the evaluation of numerous observations, a differentiation between two ranges is made.

Specific Film Thickness $\lambda > 2$. In general, the tooth flank surfaces are separated by a sufficiently thick hydro- or elastohydrodynamic lubricant film. The viscosity of the applied lubricant is the decisive property of the lubricant. Only little wear occurs in the long term. Surface damage is not to be expected.

Figure 46. Load and speed distribution in tooth contact according to: A, beginning of tooth engagement; B, beginning of single-tooth engagement; C, pitch point, no sliding velocity; D, end of single-tooth engagement; E, end of tooth engagement; DTE, double tooth engagement; STE, single tooth engagement; F_{ZE}, tooth force within tooth engagement line; F_{Zmax}, maximum tooth force within tooth engagement line; v_Σ, hydrodynamic effective velocity; v_g, sliding velocity; v_t, circumferential velocity.

Specific Film Thickness $\lambda < 0.7$ (Borderline). Numerous industrial gears are operated in this range which is also called borderline lubrication. Falling below the critical value leads to an increased risk of surface damage as well as increased wear. In this range, the right lubricant in connection with a suitable lubricant additive system is particularly important.

If borderline lubrication is reached in the tooth contacts, the tooth flanks have to be protected against direct metal-to-metal contact in order to avoid tooth damage.

With sufficiently large film thickness rates ($\lambda > 2$), the effect of the lubricant viscosity is sufficient. In slowly running gears connected with low oil sump temperatures and low circumferential velocities, the lubrication conditions during borderline lubrication ($\lambda < 0.7$) is generally improved by using polar oil compounds, fatty acid or solid matter particles (molybdenum disulfide, graphite etc.). Due to the low circumferential speeds, the mentioned compounds can form physical deposits on the surfaces and develop a permanent protective layer.

In quickly running gears, in connection with relatively high oil sump temperatures and high circumferential velocities, EP additives improve the lubrication effect during borderline lubrication ($\lambda < 0.7$). Depending on the contact temperature, the EP additives begin a chemical reaction with the surface of the tooth flanks. This reaction leads to the generation of metallic soaps which serve as a slide layer, thus preventing metal contact.

9.3.2. Specific Gear and Transmission Failure

When constructing a gear, it must, first of all, be ensured that all sliding rolling contact points, especially the toothings, are supplied with sufficient quantities of lubricant in all operation modes. If this is the case, significant failures in the toothings, with the exception of corrosion or the like, will normally not occur in non-loaded gears. Failures in toothed wheels are always the result of excessive load, i.e., a too high local load of the respective material – lubricant combination.

Toothed wheel damage influenced by the lubricant is divided into three categories: Wear, scuffing and scoring, and fatigue (micropitting and pitting) [239].

Wear (→ Abrasion and Erosion). Continuous wear is predominantly observed at low circumferential velocities and during borderline lubrication, see [240].

The wear of a toothing can be significantly influenced by hardening the toothed wheels and selecting a suitable lubricant.

Scuffing and scoring of tooth flanks occurs predominantly at medium to high circumferrential velocities and in case-hardened toothings. According to [241], [242] the contacting surfaces weld together for a short time. The high relative velocity of the contact surfaces towards each other breaks this welded joints immediately, thus causing the typical scuffing and scoring phenomenon.

Scuffing is a very sudden damage which can already be caused by one single overload. Sudden scuffing can lead to the total destruction of tooth flanks.

Freshly produced toothed wheel surfaces without run-in are extremely subject to scuffing. By adding to the lubricant EP additives, the scuffing load capacity can be improved by a factor of 5 and more. The calculation of the scuffing load capacity is standardized according to [235], [243].

Fatigue.

Micropitting on tooth flanks can be observed in case-hardened toothings in practically all speed ranges. Tooth flanks with rough surfaces are especially subject to micropitting. Micropitting develop predominantly in the area of negative sliding velocities or in slip areas below the pitch circle as damage due to endurance failure according to [244].

A suitable lubricant with a positive influence on the micropitting must have a sufficiently high viscosity as well as a suitable lubricant additive system. When selecting a suitable additive system, the operational viscosity or temperature of a gear is of superior significance.

Pitting is an endurance failure which is observed on both quenched and tempered and case-hardened toothings for all types of gears and at all circumferrential speed ranges [245].

Pitting is observed predominantly on the tooth flank centers in the height of the pitch circle since this is where the highest load occurs (single-tooth engagement) or the largest stress-cycle amplitudes. Here, the material shows the quickest fatigue.

Recent examinations [235], [246] have shown that, in principle, an influence of the lubricant on the pitting load capacity is possible.

In general, an increase in the lubricant's viscosity has a service-life extending effect. However, it is not always possible and reasonable to increase the lubricant's viscosity in a gear (higher splash losses). Currently, lubricants with a lower viscosity are used more and more often.

Suitable lubricant additive systems exist – above all for lubricants with a low viscosity (ATF technologies) – which have a positive impact on the pitting load capacity of the toothings [246].

9.4. Gear Lubrication Oils for Motor Vehicles

Gear lubrication oils for motor vehicles have to meet the specific requirements of the gear drives (see Section 9.2). Mostly, the gearboxes which serve to change the gear ratio are manual transmissions with synchronization. They can also be automatic or semiautomatic transmissions or constantly variable transmissions (CVT). In automatics or CVTs, the lubricant is not only responsible for the gear drive lubrication but also for the function-related operation of wet clutches, wet brakes as well as torque converters and retarders.

Today, it is not possible to meet all working, operating and ambient requirements of the mentioned transmissions with only one lubricant. Currently, more and more tailor-made individual lubricant solutions are being developed for specific applications, special transmissions and transmission family types. Like the development of new engine oils, the current development of gear lubrication oils for motor vehicles has not yet come to an end and is mainly characterized by several factors:

- The requirements and specifications issued by the motor, transmission and vehicle manufacturers intend to considerably extend the oil-change intervals. Today, most of the manual transmissions and axle gears in passenger cars are operated with oil-fills for life (250 000 km). With respect to automatic transmissions in passenger cars, these long oil-change intervals will soon be achieved. For commercial vehicles, it is planned to achieve transmission service lives of 350 000 km, 500 000 km up to 1 000 000 km without oil-change.
- The use of mineral base oils is decreasing in the industrialized countries. Today, environmentally friendly, synthetic and ester-based

base oils are often used for reasons of environmental protection. Due to the better thermal oxidation stability, ester-based oils are used together with PAO and hydrocracked base oils.

Attempts are, furthermore, made to reduce lubricant toxicity, especially the chlorine content of commonly used additives.

Modern vehicles are expected to ensure an improved performance, a reduced noise emission and a reduced fuel consumption. This trend is expressed in the increasing use of lubricants with a low viscosity together with a reduced fill volume. Furthermore, multigrade oils are currently used on a large scale to considerably reduce the fuel consumption.

9.4.1. Lubricants for Gear Drives in Commercial Vehicles

Commercial vehicles are divided into so-called light trucks with a maximum load of 3 to 6 t and heavy trucks with a maximum load of more than 6 t. In 1999, the worldwide annual demand for gear lubrication oils for commercial vehicles amounted to approximately 647 000 t. In the same year, some 1.84×10^6 commercial vehicles were produced in Western and Eastern Europe, which corresponds to drive-line lubricant volume demand of 140 000 t of gear lubrication oils for the commercial vehicles' gearboxes and axle gears for the European market. In 1999, the number of manufactured light trucks amounted to some 1.505×10^6 vehicles.

Because the fill volume per transmission unit is two to six times larger and amounts to 10 to 30 L, heavy trucks are far more interesting for the oil manufacturers. At the same time, the oil development also confronts a bigger challenge in meeting the requirements made on the oils used in the commercial vehicles' large transmissions. In 1999, the number of manufactured heavy trucks amounted to approximately 335 000 in all European countries.

Tables 22 and 23 list the most important current (2000) specifications issued by the transmission manufacturers and automotive companies, split into manual transmission and rear axle gears for heavy trucks. With respect to the specifications, the modified new SAE classes are to be taken into account. Above all, the new classification SAE J2360 is to be mentioned which will replace the old MIL-PRF-2105E. In addition to this, the new SAE 'Automotive Gear Lubricant Viscosity Classification' is also to be taken into account.

Table 22. Specifications for lubrication oils for rear axle gears of commercial vehicles

Daimler – Chrysler 235.8	SAE 75W-90, extended drain, 250 000 km to 300 000 km
Volvo transmission oil specification 97312, STD 1273,12	SAE 75W-80/85 for transmissions made by Meritor extended drain, 400 000 km or 3 years
MAN 342 SL (synthetic, long distance)	extended drain, 320 000 km
Scania STO 1:0 (part synthetic, synthetic)	API-GL5+, extended drain, more than 120 000 km
RVI-TDL axle	SAE 75W-90, extended drain, 350 000 to 400 000 km or 2 to 3 years
ZF TE-ML 12 A-C (mineral, part synthetic)	extended drain, 120 000 km
ZF TE-ML 12 D (synthetic)	extended drain, 300 000 km

Table 23. Specifications for manual transmission gears of commercial vehicles

Daimler – Chrysler 235.11	SAE 75W-80/90, extended drain, 250 000 to 300 000 km
Volvo Transmission Oil Specification 97307, STD 1273,07	SAE 75W-90, extended drain, 400 000 km or 3 years
MAN 341 SL (synthetic, long distance)	for gears made by ZF and Eaton, extended drain, 320 000 km
MAN M 3343 mL/SL (mineral, synthetic, long distance)	total drive-line oils, extended drain, 180 000 km
RVI-TDL gear box	SAE 75W-90, extended drain, 350 000 to 400 000 km or 2 to 3 years
ZF TE-ML 02 A – C (mineral, part synthetic)	extended drain, 160 000 km
ZF TE-ML 02 D (synthetic)	extended drain, 300 000 km

This trend in the development of lubricants for commercial vehicles leads to a significant change in the current ratio between service fill and relubrication on the one hand and the factory fill on the other hand. The proportion of the service fill and relubrication of currently 75 % – with a factory fill proportion of 25 % – will be reduced to 20 % for the service fill and relubrication – with a factory fill proportion of 80 % during the next ten years.

All mentioned specifications constitute a challenge for the development of gear lubrication oils for commercial vehicles. Apart from the very high chemical and physical requirements

included in these specifications concerning the oxidation stability (test at 150 – 160 °C), corrosion, filterability, foam etc. (see Section 9.6) the mentioned specifications include a large number of mechanical – dynamic tests and require very high safety levels with respect to the scuffing and scoring, pitting and wear resistance of the toothings using different, standardized, nonstandardized and company-internal test procedures. This makes the development of new oils increasingly complicated and expensive. A particular obstacle in the development of oils for commercial vehicles is the improvement and optimization of the synchronization behavior during upshift or downshift operations.

Although many commercial vehicles of American manufacturers still do not use synchronized transmissions, almost all commercial vehicles in Europe are equipped with these transmission systems. The SSP 180 test bench has proven very successful in the oil development for a sufficient synchronization behavior, see also page 173.

The main problem in the oil development is to adjust the same friction or friction constancy during a required gear service life of approximately 100 000 gearshift operations with different material – lubricant pairs without significantly changing the other chemical – physical and dynamic – mechanical properties.

9.4.2. Lubricants for Gear Drives in Passenger Cars

The development of passenger cars is mainly influenced by the worldwide fierce competition of numerous producers. For the oil producers, this means to supply approved lubricants which have to be available in the same quality worldwide or at least in the production locations for gear-filling purposes.

A passenger car's sportiness requires a high performance and a high torque in identical or even smaller spaces for gearboxes. Due to the economy required at the same time, the lubricants are expected to optimize the total efficiency of the engine and total drive-line without having to be changed during the entire service life of more than 250 000 km.

The higher performance causes an increased heat development in the transmissions which accelerates the aging of the gear lubrication oils. The design of new vehicles leads to the development of carefully selected bodies, often with a low air resistance. This is often connected with an inferior air circulation and cooling of the transmissions. Additional capsules facilitate the reduction of driving-related noise to increase the driving comfort. At the same time, the poor heat dissipation leads to a heat stowing in the capsular spaces. Especially these factors increase the temperature in the vehicle's transmission and aggravate the operational conditions, thus facilitating the aging behavior of the oil.

New passenger cars include transmissions with a higher number of gear stages so that today passenger cars using gear drives with six stages are not unusual. To achieve this, all technical possibilities of dimensioning and material have to be exploited. This always has an effect on the corresponding lubricant when new lighter or more solid materials have to be used in the transmission as new friction partners with a friction and wear behavior so far unknown.

An increasing number of vehicles utilizes automatic transmissions and four-wheel drive systems. The necessary control elements and sensor systems consisting of electric components such as measuring units and sensors etc., are installed in the vehicles' transmissions. The compatibility of these sensible components with the oil leads to special requirements made on the lubricant and its development.

In Europe almost 90 % of all passenger cars are equipped with synchronized manual transmission systems. The variety of the friction material partners used in the synchronization of passenger cars is constantly increasing so that here more and more individual solutions are also required with respect to the lubricant. Another requirement on the gear lubrication oils for manual transmission systems, as well as for rear axle gears, is the very high scuffing resistance to ensure the protection of the spur gears' which have significantly more sliding proportions than the planetary gears' toothings normally used in automatic transmission systems.

All mentioned development trends are reflected in the increasingly stricter specifications and test procedures issued by leading automotive companies.

Several important specifications for lubrication oils for manual transmissions and transaxle

drive system gears for passenger cars are listed below:

VW, Seat, Skoda, Audi, TL 726, API GL 4 SAE 75W/SAE 80W (lifetime gearoil for manual transmissions and transaxles)
Daimler – Chrysler page 235.10
Volvo STD 1273,08
VW TL 52157 (75W 90, synthetic lifetime)
VW TL 52171 (75W, synthetic lifetime)
VW TL 52178 (75W, mineral lifetime)
Ford factory fill for life M2C 200C
BMW 602 00.0 (synthetic lifetime)

9.4.3. Lubricants for Automatic Transmissions and CVTs

The most important consumers of lubricants for automatic transmission and drive systems (ATFs) are off-highway vehicles and machines as well as commercial vehicles, mainly buses. In addition to this, ATFs are also used to fill power steering transmission systems in trucks, commercial vehicles and passenger cars.

90 % of all passenger cars on the North American and Asian vehicle market utilize automatic transmission systems. The total estimated ATF volume worldwide for the year 2001 amounts to approximately 992 000 t. The total volume breaks down as follows: North America (61 %), Asia Pacific (15.5 %), Europe (12.5 %), Latin America (8.8 %) and Middle East (2.2 %).

Most manufacturers of automatic transmission systems prescribe fluids for the application which meet the listed specifications:

Ford Mercon (revised September 1992)
Ford MerconV
GM Dexron II D
GM Dexron II E
GM Dexron III
GM Dexron IIIG
Allison C-4
Daimler – Chrysler 236.2
Daimler – Chrysler Mopar ATF3+, Mopar ATF 4+
Leyland E85

These specifications refer to the Asian, North American and European markets and to the business for service fill and relubrication of vehicles. Currently, the factory fill is subject to stricter specifications:

General Motors, Factory Fill GM 6418-M
Ford Factory Fill for Life, M2C 202B
Daimler – Chrysler Factory Fill for Life, MS 9602

European manufacturers of vehicles and, especially, transmission systems have issued particular specifications mainly for off-highway construction machines and commercial vehicles:

ZF TE-ML-14, Standard drain, 60 000 km
ZF TE-ML-14, Extended drain, 120 000 km
Voith G607, Standard drain, 60 000 km
Voith G1363, Extended drain, 120 000 km
Renk standard drain
Daimler – Chrysler 236.8
VW TL 52178

Worldwide, there are further specifications for off-highway construction machines and commercial vehicles with importance for the oil development:

Caterpillar TO-4
ZF-TE-ML 03
ZF-TE-ML 09
Komatsu
Komatsu – Dresser

ATF Lubricant Requirements for Hydrodynamic Transmissions. Automatic transmissions make use of the versatile possibilities of often series-connected hydrodynamic transmissions for the torque transfer and conversion. The hydrodynamic clutches facilitate an improved and smooth driving and operating behavior, especially with respect to heavy vehicles with a high inertia mass. A hydrodynamic transmission displays a constantly variable operation, whereby the resulting torque independently adapts to the respective load status by changing the rotational speed.

Apart from the hydrodynamic start-up clutches, hydrodynamic brakes, the so-called retarders and intarders are used, especially in commercial vehicles. They serve to limit the output speed when driving down long slopes in order to reduce the load on the vehicle's brakes or to go easy on them.

The fluid machines ensure the uncoupling of the drive-line and output torque and, thus, a constantly smooth and comfortable force transfer in

the drive shaft. They will, however, only work adequately with slip and are, thus, characterized by significant fluid losses. Apart from the larger weight, this constitutes another reason for the generally higher fuel consumption of vehicles with automatic transmissions in comparison to vehicles with manual transmissions.

During start-up procedures and permanent operation as well as during braking procedures, the lubricant as a force transfer medium in the hydrodynamic transmissions is subject to an extremely quick generation of heat and load despite installed radiator systems in comparison to gear drives. Due to the function-related fluid losses, hydrodynamic clutches, torque converters and brakes always require low-viscosity, mildly added gear lubrication oils with a high oxidation resistance. Short-term oil temperatures of more than 160 °C during the operation of a vehicle are not unusual. Especially for these fluid machines, a good viscosity – temperature behavior, corrosion protection, optimal foaming behavior and air separation properties are a must. With respect to the viscosity and $V-T$ behavior lubrication oils for automatic transmissions are very similar to engine oils.

To facilitate the distinction between ATFs and the engine oils, ATFs are always dyed with red color.

ATF Lubricant Requirements for Wet Clutches and Brakes. Like in the synchronization, the friction characteristics are of great importance for a comfortable and regular gearshift behavior during the transmission's entire service life in wet clutches and brakes as well. A wet clutch or brake consists of disk-plate fin blocks. The clutches and brakes are opened and closed hydraulically. Apart from the desired friction characteristics, the oil predominantly serves to ensure the cooling of the friction partners. Often the oil is injected from the interior into the disk-plate blocks via the rotating shaft.

To adjust a lubricant to a desired friction behavior or friction characteristic, a test in the machine or, at least, a test of the disk-plates fins used later in the machine is required. Therefore, test benches have been developed especially for this purpose which enable a more precise adjustment of the gearshift behavior to the selected material – lubricant combination.

A tester which demonstrates the different sliding – friction behavior of oils is the low-velocity friction apparatus (LVFA). Figure 47 gives an example of measured friction behavior for some lubricants as a function of the sliding speed.

Tests of original disk-plates can also be carried out using an SAE No. 2 tester or a DKA friction test bench. These testers work with given centrifugal masses which reduce the speed of the disk-plate blocks under defined test conditions. Static and dynamic friction coefficient and friction losses are determined using a high-resolution measuring technology.

According to the definition, the static friction is measured during the tests at low differential rotational speeds ($< 2\,\mathrm{min}^{-1}$) or towards the end of the gear-shifting operation.

To test the gearshift and friction behavior, especially in case of permanent slip of the friction partners, the transmission manufacturer ZF has developed another test bench. The so-called GK test bench or CSTCC (continuously slipping torque converter clutch) enables the simulation of almost all real operating conditions. Even slip-controlled clutches of hydrodynamic clutches and torque converters can be simulated using the GK test bench. Figure 48 shows possible operating conditions.

Gear Lubrication Oils for CVT Applications. Constantly variable transmissions in motor vehicles enable the operation of a combustion engine along certain preferred characteristic curves in the torque – rotational speed field. In contrast to all other vehicle transmissions, the CVT enables an ideal alignment of the supply field of a combustion engine with the request field of the vehicle.

Up until today, mainly three constantly variable transmission concepts have proven to be successful to meet these requirements.

B-CVT Belt Drives. For passenger cars with a low or medium drive power of up to 150 kW, the belt drive, mostly a 'Van Doorne' belt, has been very successful (Fig. 49). The belt embraces the cone pulleys which have been hydrostatically and axially applied to the drive and output shafts. Thus, the radii of the belt drive's course as well as the gear ratio can be varied constantly.

Figure 47. LVFA (low velocity friction apparatus)
Determination of the dependence of friction coefficient on sliding velocity to avoid stick – slip behavior

Figure 48. GK test bench. Test runs, variety of operating conditions
A) Opening and closing; B) DKA operation (limited); C) Similar to LVFA;. D) Static operation (friction vibrations)

For the instationary slide – roll contacts between the belt drive and the cone's contact surface, the lubricant is an extremely important construction component. The contact points are often subject to very high contact temperatures and mixed-lubrication conditions. Here, a very good wear protection of the oil against the extremely hardened surface of the cone pulleys is required. In addition, the cone's finely ground contact surfaces require from the lubricant a very high pitting load capacity. On the one hand, a slip of the belt drive due to insufficient contact pressure forces should be avoided by means of control engineering. This cannot be avoided totally. Accordingly, the lubricant also has to ensure a sufficient scuffing load capacity for these operating conditions.

Figure 49. Adjusting device – principle of a B-CVT (Van Doorne Belt)
A) Gear ratio in position LOW; B) Gear ratio in position TOP

Nearly all belt drives of vehicles have a toothed wheel gear stage as well as a hydrodynamic start-up clutch. In order to increase the driving comfort and reduce the losses, slip-controlled clutches are used. Thus, the same requirements apply for both CVT oils and ATFs. Currently, CVTs are filled with ATF oils which are slightly modified lubricant variations or have been individually adjusted to the respective CVT. The viscosity, additives and base oils are very similar to ATFs, however, the so-called friction modifiers are of a greater importance.

T-CVT Traction Drives. The belt drive system's mechanics has reached its limits in power transmission at a driving power of slightly more than 150 kW, i.e., in mid-range passenger cars or limousines. Currently, constantly variable transmission concepts are tested in this respect which are based on so-called traction drives (Fig. 50).

The constantly variable adjustment of a traction drive takes place by tipping the transmission or idle wheels which, axially pressed together, roll on the semi or full-toroids' courses in a force-conclusive way. In traction drives as well, the lubricant is to be considered an important construction component and is as significant as the material, the surface treatment and the hardening of the rollers and toroids. Of all transmission types, semi and full-toroid transmissions stand out due to the highest surface pressure and circumferential speeds in the slide – roll contact points. Surface pressures of 4500 N/mm^2 and circumferential speeds of approximately 50 m/s in traction drives are not unusual.

In traction drives, the friction depends heavily on the oil, the material pair and the slip. Mainly those lubricants are used which enable a high transmission performance at the lowest slip possible, thus having a high friction coefficient.

Adequately added, naphthene-based hydraulic fluids have proven very successful for these applications. However, synthetic cycloaliphatic oils with a particularly high friction coefficient are even more suitable for these purposes. When using traction fluids in transmissions, e.g., in roller bearings and toothed wheels connected in series, the higher friction, however, leads to excessive and undesired overheating.

Another disadvantage of the traction fluids is a relatively low flash point of 130 to 150 °C. Therefore, the very high contact temperatures in

Figure 50. Adjusting device – principle of a T-CVT (traction drive)

the slide – roll contacts cause undesired evaporation losses.

Hydrostatic dynamic powershift drives are used in agriculture and in tracked vehicles with a usually very high drive power of more than 300 kW. In these transmission systems, planetary gear stages branch some of the drive power into a closed hydrostatic circulation system consisting of a controllable adjustment pump, mostly an axial piston pump, and a hydrostatic constant engine, mostly with inclined axles. The branching of the power and the control of the output speed depending on the volume flow takes place through the adjustment of the axial piston pump. These transmissions are always adjusted variably and under load in the entire adjustment range.

The requirements made on the lubricants used in this respect are limited to the toothings, roller bearings and hydraulic systems. For reasons of pumpability, the very good $V-T$ behavior of the low-viscosity hydraulic oils used is of great importance. In addition, these transmissions are to be protected against wear and corrosion using a suitable lubricant. ATFs are also often used.

9.5. Multipurpose Lubricants in Vehicle Gears

Multipurpose lubricants are used in agricultural and working machines such as tractors, harvesters, etc.

In these vehicles, the long-term and perfect function of the wet, force-conclusive additional clutches and brakes is to be ensured. The scuffing load capacity of the balancing hypoid transmissions is to be guaranteed using a suitable lubricant. Friction, hydraulic and wear requirements have to be met. In order to ensure the driving operation even at low temperatures, torque converters have to work adequately and safely, even under conditions of permanent slip of the wet clutches. Therefore, multipurpose oils have almost always a low viscosity and stand out due to a very good $V-T$ behavior. The presence of water and dirt has a significant impact on these oils, especially in respect of their foaming behavior.

This is aggravated by the fact that the mentioned requirements often have to manage with only one oil circulation system.

Against the background of these requirements it is easy to understand that major manufacturers of tractors and agricultural machines, such as Ford, John Deere and Massey Ferguson, have developed their own lubricant specifications for UTTOs and STOUs. The most important of these specifications are listed below:

UTTO Specifications
- Massey Ferguson M1127A
- Massey Ferguson M1127B
- Massey Ferguson M1135
- Massey Ferguson CMS-M1143 Limits
- Ford ESN-M2C-86C
- Ford ESN-M2C-134D
- John Deere J20C
- John Deere J20D
- MS 1207

STOU Specifications
- Massey Ferguson CMS-M1139
- Massey Ferguson CMS-M1144 Limits
- Ford ESN-M2C-159-C
- John Deere J27

9.6. Gear Lubricants for Industrial Gears

Industrial gear applications differ from vehicle transmissions mainly due to their larger variety and higher number of combinations of toothing types and sizes used (Fig. 45). Most important are worm gears, planetary gears and helical spur gears with crossed axis. Gears for industrial application are also applied in a larger variety of possible working and ambient conditions. They stand out due to much higher torque and performances, connected with clearly larger housing dimensions. At the same time, the gears size also requires larger lubricant quantities. The service life requirements on industrial gears are clearly higher than those made on vehicle transmissions (see Fig. 43).

In comparison to vehicle gear lubricants, industrial gear oils meet less requirements at one and the same time. With respect to industrial applications, the user has mainly to regularly and punctually change the oils used in accordance with the instructions of the oil producers. In addition, once-through lubrication is often applied. In this respect, the environmental compatibility of the lubricants used should especially be taken into account.

In opposite to vehicle gears, the type of lubrication in industrial gears can also be very different. Usually, vehicle gears are equipped with an oil immersion or injection lubrication system. According to their working conditions, industrial transmissions can, however, be lubricated manually by dropping or pouring, operating in an oil sump, through oil mist or – as well – through an oil injection system. Often larger oil lubrication systems are employed, e.g., in printing presses or paper machines, with fills of several hundreds of liters of lubricant. Figure 51 gives a schematic overview of a lubrication system commonly used today.

During the lubrication with an oil lubrication system, the total volume of the oil must not be selected in a too low quantity so that the air in the oil can be released. In this respect, the oil's air separation and foaming properties play a very important role since air is a bad lubricant. The purity of the lubricant during the operation of these systems is another central factor with respect to the gear's service life and, thus, the oil's filtration and filterability.

The viscosity-dependent pumpability of the oil, especially at cold temperatures as well as during the start-up of such systems, is also to be taken into account precisely. The wrong viscosity selection of a lubricant can lead to the standstill of the entire system. A guideline for the adequate viscosity selection as a function of load and speed for spur gears and worm gears in industrial applications is given in [247].

In comparison to the lubrication oils for vehicles transmissions, the worldwide number of specifications concerning the properties of the lubricants for industrial applications is quite small. Important specifications issued by the gear manufacturers and end consumers are listed below:

David Brown S1.53101 (Jan 1985)
U.S. Steel 224
DIN 51517 part 1 to part 3
Flender sheet A, 02.03.1999, Rev. 0

These specifications cover both simple mechanical – dynamic model test procedures and common component testers and test standards with roller bearings and toothed wheels. Apart from these specifications used worldwide, many transmission and system manufacturers are currently issuing their own, more sophisticated specifications for their industrial gears with increasing requirements.

***V – T* Behavior and Viscosity Index.** According to the ambient and operating conditions, the required $V-T$ behavior of gear lubrication oils constitutes a very important requirement during the application. Here, the base oil's properties according to the viscosity range is of great importance. Worldwide, the lubrication oils for industrial gears are subject to the ISO viscosity grade conversions. In the American region as well as in a large part of the automotive industry, the SAE gear viscosity numbers apply. In the American and, mainly, in the Asian regions, the viscosity ranges for AGMA lubricant are used most often.

Corrosion and Rust Protection. Especially corrosion and corrosion protection play a very important role with respect to lubrication oils for industrial gears. Due to the required long service lives of industrial gears, severe corrosion can facilitate an unexpectedly quick failure

Figure 51. General layout of a lubrication system for large industrial gears

of bearings, toothed wheels and other important gear components. This has to be avoided by using a protecting lubricant combined with a suitable additive. Some industrial applications are aggravated by the presence of salt water in the gear, thus requiring special test methods.

Oxidation Stability. The aging behavior of a lubricant is connected with a change in viscosity and with an increase in the acid number. Today, sensitive gears are often tested on a regular basis. Should the acid number change noticeably, the oil producers recommend an oil change.

Flash Point and Pour Point. According to the application, the specifications almost always define applicable flash and pour points.

Demulsibility and Water Separation. Often the water cannot be prevented from penetrating the lubricant. Once the water proportions in the oil have exceeded a certain limit, the only possibility left is to change the oil or to separate oil and water. In large oil systems, the water will sink to the bottom of the oil tank due to the higher specific weight and can be released through a drain cock. This, however, requires a good water separation behavior of the lubricant.

Air Separation. Naturally, air is mixed into the oil in each gear. Since air is also a poor heat conductor, the air should be separated from the oil as quickly as possible in order to minimize the air's proportions in the oil.

Paint Compatibility. Because of the improved protection and extended service life, the interiors of large industrial gears are also coated with paint which can be attacked, softened and stripped off by oils. This applies especially for one-component paints whereas two-components paints are generally resistant against polyalkylene glycols.

Seal Compatibility. Like paints, seals often have organic components which can be attacked by lubricants. The risk of an attack rises considerably with an increase in the oil temperature. The elastomer compatibility tests of important specifications for the combination of lubricant and seal include both static and dynamic tests.

Foaming. Especially contamination cause the development of partly large quantities of foam in oils. This foam development can reach dimensions so that the foam escapes the gear through de-aerators, thus resulting in a contamination of the environment. In order to avoid this, only those oils should be used which in their fresh condition stand out due to a very low foaming tendency.

Environmental and Skin Compatibility. Today, especially the environmental and skin compatibility is considered very important by a growing number of gear manufacturers and system operators due to the effect on health and environment. Numerous specifications require compatibility tests.

Open gear drives are often found in the cement industry – the so-called milling gears – in rotary kilns in the iron and steel industry, in coal-burning plants or in open-cut mines. These open large gears are often lubricated with sprayable adhesion lubricants. Apart from the requirements made on the load capacity and wear protection, priority is also given to the adhesion properties, sprayability, pumpability and corrosion protection. In the mentioned systems, solid so-called compounded lubricants have proven to be successful as additives to such adhesion lubricants. Today, the health and environmental impact which can occur in oil mist and spray lubrication systems as well as the direct losses due to oil-containing waste air minimize careful oil separation processes. Open gears can also be lubricated manually or with the help of dosing pumps in regular intervals with high-viscosity oils.

10. Compressor Oils

10.1. Gas Compressor

10.1.1. Displacement Compressors

Reciprocating Piston Compressors. In reciprocating piston compressors the oil is also subject to enormous stress resulting from the high temperatures created when the medium is compressed (which can cause oxidation and lead to deposits) and in the case of air, the oxygen enrichment. The cleanest possible air or gas should be compressed because contaminants can accelerate oxidation and wear. In the case of drive unit lubrication, the lubrication of the bearings is of primary importance.

For reciprocating piston compressors, normally, lubricants based on mineral oil according to DIN 51 506 – VCL, VDL (or PAO- or diester-based lubricants) are used with viscosity grades of ISO VG 68 to ISO VG 150. Mobile compressors are often lubricated with monograde engine oil (SAE 20 – SAE 40) [250], [251]. Small to medium-sized piston compressors are used for pressures up to 10 bar.

Rotary Piston Compressors, Single Shaft, Rotary Vane Compressors. The pressure chambers of rotary piston compressors are cooled and lubricated by total-loss systems or by direct oil injection. The lubrication of rotary piston compressors is similar to the lubrication of the cylinders in reciprocating piston compressors insofar as the lubricant is subject to high outlet temperatures in both cases. In the case of oil-injected and oil cooled rotary piston compressors, a quantity of oil is continuously injected into the compressor chambers. The quantity of the oil is such that the outlet

Table 24. Overview of normally used compressor oils. The viscosity and the quality recommendations of the compressor manufacturers must be taken into consideration.

Viscosity classification	Type piston compressors[a]	Screw compressors oil-injected	Sliding vane compressors[a,b]	Turbo compressors (axial and radial)[c]
ISO VG 32		MO HC-oils PAO		TDL 32 TDL 32EP synth. oils
ISO VG 46		MO HC-oils PAO POE		TDL 32 TDL 32 EP synth. oils
ISO VG 68 (SAE 20W-20)	MO PAO diester	MO HC-oils PAO POE	MO diester HC-oils	
ISO VG 100 (SAE 30)	MO PAO diester		MO diester HC-oils	
ISO VG 150 (SAE 40)	MO PAO diester			

MO = mineral oil; PAO = polyalphaolefin; HC = hydrocracked oil; POE = biologically degradable polyol esters.
Diester, polyolester and PAO: for very hard working conditions, increase of service intervals is possible.
HC-oils: for medium and hard working conditions.
MO: for normal and medium working conditions.
Lubricants for roots-compressors: HL, CL, CLP; ISO VG 100-150, DIN 51 524, DIN 51 517.
Lubricants for vacuum pumps: ISO VG 68-150.
[a] Total-loss lubrication: HD-monograde motor oils HD 20W-20, HD 30, HD 40.
[b] For oil-injected compressors in mobile equipment (e.g., railways, buses): multigrade motor oils (e.g., 10 W 40, 15 W 40). For oil-injected compressors in stationary units: turbine oils according to DIN 51 515 TDL, air compressor oils according to DIN 51 506 VCL, VDL. For hard working conditions: monograde motor oils HD 20W-20, HD 30, MIL 2104 D.
[c] Turbine oils according to DIN 51 515 TDL or TDL-EP with extreme pressure additives.

temperature does not exceed 100 – 110 °C. At the same time, it seals the pistons against the housing and protects against wear. The cooling of the medium results in an increase in compression performance. Cooling and sealing increase the volumetric efficiency and thus the overall efficiency of the compressor. The oils used are normally VCL or VDL according to DIN 51 506 with an ISO VG between 68 and 150 or monograde SAE 20 – SAE 40 engine oils .

Screw Compressors. In lube-injected screw compressors, the oil has a lubricating, sealing and cooling function. The lubricant is injected into the pressure chamber between the rotors at about 3 – 4 bar. It then forms a hydrostatic and a hydrodynamic lubricating film. The oil therefore lubricates the meshing rotors and the plain and roller bearings which are part of the geared coupling. Furthermore, it seals the gaps between the rotor and the housing. It also helps absorb heat and dissipate this via radiators. The temperature of the compressed air of about 80 °C to 100 °C is adjusted by the quantity of oil injected. Downstream oil separators (normally cartridge filters) remove the oil from the air.

As the viscosity of the oil is of primary importance to elastohydrodynamic lubrication and thus for the mechanical stability of the film, it must be matched to start-up and normal running conditions. As a rule, ISO VG 46 lubricants cover most manufacturer's recommended viscosity thresholds of about 10 mm^2/s at operating temperature to about 500 mm^2/s when starting-up. This range also satisfies most applications in central Europe. Higher viscosity ISO VG 68 oils or synthetic ester-PAG or PAO-based lubricants are used in countries with high ambient temperatures. In recent years, lubricants based on hydrocracked oils have found increasing acceptance.

Roots Compressors. Recommended lubricants include DIN 51 517 CL and CLP or HD SAE oils in the viscosity grades ISO VG 68 and ISO VG 100 [250].

10.1.2. Dynamic Compressors

Turbo Compressors. The oils for turbo compressors lubricate bearings, radial shaft seals and possibly gears via a positive-feed circuit. In some cases, the bearings are lubricated with grease. Ideally, the same lubricant should be used for the compressor and its drive. Most often, DIN 51 515 TDL 32 and TDL 46 turbine oils or TDL-EP grades.

Turbo compressors are principally used for creating compressed air in mines and industrial manufacturing plants [249], [250].

10.1.3. Preparation of Compressed Air

The oil injected into oil-cooled screw and rotary piston compressors is always removed from the compressed air. The oil which is mixed with the highly compressed air is removed and collected in single or multistage downstream oil separators. Before the oil is re-circulated, it is filtered and cooled. Depending on the specific requirements, the compressed air may then pass a number of subsequent treatment stages such as refrigerant dryers or absorption dryers. Very low residual oil quantities in the air can be achieved by the fitting of a series of in-line oil separators [252–254].

10.1.4. Oils for Compression of Other Gases

Oxygen Compressors. Because of explosion hazards when oxygen is compressed, pressure chambers lubricants must be mineral oil-free. Water and water-based solutions such as glycerol can be used for cylinder lubrication. Mineral oil-based products may be used for compressor drives if it does not come into contact with the pressure chambers [250].

Acid Gas Compressors. Gases often contain acidic components such as SO_2 or NO_x. If standard compressor oils were used for such applications, the lubricating oil would soon become over-acidified. To counter this, lubricants are used for such applications which contain highly alkaline additives. These components can neutralize the acidic components in the gas. In these cases, it is recommended that monograde engine oils (20W-20, 30W, 40W) with high alkaline reserves (high TBN) are used [250].

Inert Gas Compressors. When inert gases are compressed, the same rules as for air compressors should be used [248], [250].

Hydrocarbon Compressors. Hydrocarbons such as ethane, propane etc. are easily soluble in mineral oil. This causes the viscosity of the lubricating oil to fall if mineral oil- based products are used. For this reason, higher viscosity mineral oils such as ISO VG 100 and ISO VG 150 must be used in piston compressors whose crankcases are subject to low inlet pressures ($1-3$ bar). In the case of screw compressors (high pressure; $10-15$ bar), ISO VG $68-100$ ester- or polyglycol-based lubricants with lower hydrocarbon solubility are recommended [248], [250].

Vacuum Pump Lubrication. Vacuum pumps are compressors whose inlet is connected to the chamber where the vacuum is created. VDL compressor oils can be used for low vacuums. Greater vacuums require synthetic oils with low vapor pressures (mostly synthetic ester oils). The lubricant selection must consider if the medium to be extracted is not air, but for example a refrigerant. In such cases, a compatible refrigerator oil can be used [250].

10.1.5. Characteristics of Gas Compressor Oils

Compressors whose chambers are lubricated pose particular safety problems if air or aggressive gases contact the lubricant. The selection of the most suitable lubricant depends on the type of compressor in question, the pressures involved, the outlet temperatures and the type of gas being compressed. Piston compressors which generate the highest pressures are particularly problematic. Turbo compressors which only have lubricated bearings and non-lubricated pressure chambers pose the least problems. Rotary and screw compressors with outlet pressures under 10 bar and correspondingly low outlet temperatures are examples of average compressor lubrication application. Table 24 shows an overview of normally used compressor oils.

10.1.6. Standards and Specifications of Compressor Oils

DIN 51 506 describes the classification and requirements of lubricating oils which are used in piston compressors with oil-lubricated pressure chambers (also for vacuum pumps). Lubricants for screw and oil-injected rotary vane and screw compressors are not included in DIN 51 506 [251]. Table 25 shows the classification of air compressor oils according to DIN 51 506. Tables 26, 27, and 28 contain the minimum requirements of air compressor oils according to DIN 51 506.

Table 25. Classification of air compressor oils according to DIN 51 506 – Table 1, September 1985

Maximum compressed air temperature, °C		
Lubricating oil category	For compressors on moving (mobile) equipment for brakes, signals and tippers	For compressors with storage tanks and pipe network systems
VDL	up to 220	up to 220
VC	up to 220	up to 160[a]
VCL		
VB	up to 140	up to 140

[a] Rotary multi-vane compressors designed for a once-through lubrication can be operated at compressor end temperatures of up to 180 °C using lubricating oils doped in the same manner as motor lubricants or doped compressor oils, provided that the requirements specified for VCL lubricating oils in table 2 are complied with.

According to this standard, such lubricants are pure mineral oils or mineral oils with additives to increase aging resistance and corrosion protection. The classification of the lubricants depends on the expected outlet temperatures and the general application. DIN 51 506 differentiates between lubricants for mobile applications and stationary applications with reservoirs. Principal differences between the listed groups: VB/VBL, VC/VCL as well as VDL are the use of oxidation and corrosion inhibitors, aging stability and residue formation and the quality of the base oils (cuts). The difference between group VB/VBL and group VC/VCL lies in the aging behavior (formation of Conradson coke after air-induced aging). Group VDL oils have to pass a more difficult aging test (formation of Conradson coke after air-induced aging in the presence of ferrous oxide). DIN 51 506 VDL oils display the best thermal and oxidation stability and form the least residues. The selection criteria in DIN 51 506 were adopted into the 1983 ISO/DP 6521 draft [251], [255]. Table 29 defines the requirements of air compressor oils for reciprocating piston compressors.

The selection criteria for screw compressor and piston compressor oils differ greatly. In oil-flooded rotary vane and screw compressors, the injected oil is constantly in contact with the 80 – 100 °C hot medium being compressed. The compressed medium and the oil are well mixed and the oil has to be separated by downstream separators and filters. This places special demands on the lubricant. On the whole, these include low foaming, excellent air release and good demulsification (separation) of condensed water. In addition of course, the specifications regarding wear protection (FZG $\geq$ 10, DIN 51 354), minimum formation of deposits, good corrosion protection etc. also apply. Most manufacturers of oil-injected rotary and screw compressors issue their own lubricant specifications. A draft of ISO/DP 6521 for oil-injected screw compressors has existed since 1983. Table 30 describes the requirements of air compressor oils for screw compressors.

10.2. Refrigerator Oils

10.2.1. Introduction

The longevity expected of refrigeration compressors is closely connected to the high quality which is required of refrigerator oils. The interaction with other substances which the refrigerator oil comes into contact with, and especially the extremely high and low temperatures, makes very specific demands on refrigerator oils.

The principal function of a compressor oil is to lubricate the pistons or rotors and to lubricate and seal the valves and, in some cases, the slip-ring seals. Furthermore, the refrigerator oil must dissipate heat away from hot compressor components and assist in sealing the compression chambers and valves. The refrigerator oil serves as a hydraulic control and functional fluid in refrigeration compressors [256], [257]. It is vital that refrigerator oil which reaches and collects in colder sections of the circuit in the form of oil vapor or oil mist or as a result of splashing must be returned to the compressor by mechanical means (oil separator) or via the refrigerant

flow (refrigerant solubility) in all operating conditions. Figure 52 shows the principle of a vapor compression refrigeration cycle.

10.2.2. Minimum Requirements

The basic requirements of refrigerator oils are laid down in DIN 51 503-1. This standard defines the basic requirements of refrigerator oils according to the medium being compressed. The introduction of new chlorine-free, polar refrigerants such as HFC R 134a (to replace CFC R 12), necessitated a revision of DIN 51 503 which appeared as DIN 51 503-1 in November 1997 [258].

Refrigerator oils are classified in alphabetical groups according to the refrigerants being compressed:

KAA Refrigerator oils not soluble in ammonia
KAB Refrigerator oils soluble in ammonia
KC Refrigerator oils for partially- and fully-halogenated fluorinated and chlorinated hydrocarbons (CFC, HCFC)
KD Refrigerator oils for partially- and fully-fluorinated hydrocarbons (FC, HFC)
KE Refrigerator oils for hydrocarbon refrigerants such as propane or isobutane

The various refrigerants available are described in DIN 8960 and the ASHRAE standard (ANSI/ASHRAE 34-1992; American Society of Heating, Refrigerating and Air Conditioning Engineers) [259].

In addition to appearance, density (ISO 3675) and viscosity (DIN 51 550), several other properties are defined and determined:

Table 28. Minimum requirements of air compressor oils according to DIN 51 506 – VDL

Lube Oil Group	VDL				
Viscosity grade	ISO VG 32	ISO VG 46	ISO VG 68	ISO VG 100	ISO VG 150

Refrigerant compatibility with R 134a ASHRAE 97/83

Table 31 gives an overview of the important refrigerants and suitable refrigerator oils on the market.

DIN 51503-2 describes criteria for evaluating used refrigerator oils [259].

10.2.3. Classification

Normally used refrigerator oils are listed in Table 32.

Dewaxed Naphthenic Refrigerator Oils. Naphthenic mineral oils are still the most significant group of oils for refrigerators using ammonia refrigerants along with CFC and HCFC (e.g., R 22). Naphthenic refrigerator oils generally display very low pour points, good cold flowing as well as high thermal and chemical stability. Selected cuts are normally used [256], [262].

Paraffinic Refrigerator Oils. Paraffinic refrigerator oils are ideal for use in R 11 and R 12 turbo compressors (ISO VG 68 and 100) because of their good $V-T$ behavior. These oils are not recommended for other compressors because of their generally inadequate solubility in refrigerants (miscibility gap, e.g., R 22). The boundaries between paraffinic and naphthenic oils are not rigid [256], [257].

Semisynthetic refrigerator oils are mixtures of highly-stable alkylbenzenes and highly-refined naphthenic mineral oils. The presence of alkylbenzenes greatly improves the solubility and thermal stability of the naphthenic components. The proportion of synthetic components is usually between 30 and 60 %. Semisynthetic oils are recommended for CFC/HCFC systems,

Screw compressors	MO AB PAO, PAG	MO AB PAO, PAG	MO AB	POE	MO/AB
	ISO VG 68-220	ISO VG 32-68	ISO VG 68-150	ISO VG 100-150	ISO VG 68
Turbo compressors	MO PAO, PAG	–[d]	MO	POE	MO/AB
	ISO VG 68-100		ISO VG 68-100	ISO VG 68-150	ISO VG 68

[a] PAG-lubricants are partly soluble with hydrocarbons (low viscosity reduction); MO, AB and PAO are highly soluble with hydrocarbons (high viscosity reduction).
[b] MO, AB and PAO are not soluble with ammonia, PAG is (partly) soluble with ammonia, ISO VG 68 is used in piston compressors, up to ISO VG 220 is used in screw compressors, please use PAG compatible components, PAG is hygroscopic
[c] PAG-lubricants are used in R 134a air conditioning systems of cars and trucks; POE and PAG lubricants are hygroscopic
[d] Normally oil-free
MO = mineral oil; AB = alkylbenzene; MO/AB = mineral oil – alkylbenzene mixture; PAO = polyalphaolefin; PAG = polyalkylene glycol; POE = polyol ester.

low- temperature R 22 systems and for drop-in refrigerants such as 401 A/B, 402 A/B and R 22 mixtures [260], [263].

Fully Synthetic Refrigerator Oils.

Alkylbenzenes. Fully synthetic refrigerator oils are based on chemically and thermally highly stable alkylbenzenes. Alkylbenzenes have been used as refrigerator oils for a number of years. Carefully selected and specially treated alkylaromatics are used. A number of complex manufacturing stages ensure that the products are free of difficult-to-dissolve waxy substances and other contaminants such as sulfur. Alkylbenzene-based lubricants display excellent solubility in CFC (HCFC) refrigerants (e.g., R 22, R 502) and mixtures thereof at evaporation temperatures down to $-80\,^{\circ}C$ (e.g., R 22).

ISO VG 46 and 68 alkylbenzenes have proved particularly suitable for use in heavy-duty ammonia compressors with very high outlet temperatures. Compared to mineral oil-based refrigerator oils, alkylbenzenes form minimal amounts of coke and slash less when starting-up.

Alkylbenzenes are also increasingly being used in hermetically sealed and semisealed compressors. Alkylbenzenes are increasingly gaining acceptance for use with drop-in refrigerants such as R 401 A/B, R 402 A/B, R 22 mixtures and together with propane/isobutane [262], [263].

Polyalphaolefins are recommended for ammonia compressors because of their good thermal stability. The formation of oxidation products (coke) is avoided even at high compressor outlet temperatures. Compared to mineral oils and particularly in the case of screw compressors, the use of polyalphaolefins can reduce the amount of oil mist and oil vapor which collects in oil separators. The amount of oil in the refrig-

erant vapor can also be reduced to a minimum. As a result of their chemical structure, polyalphaolefins display good $V-T$ behavior (high VI) and thus good cold flowing characteristics. The low pour point and low viscosity of these products guarantee satisfactory oil return even at evaporation temperatures of – 50 °C.

Polyalphaolefins of the viscosity grade ISO VG 68 are generally used in screw and piston ammonia compressors [261].

Polyol Esters. Previously used refrigerator lubricants such as mineral oils, alkylbenzenes or polyalphaolefins are not or not sufficiently soluble in the new chlorine-free refrigerant mixtures such as R 134a, R 404 a and R 507. This led to the development of synthetic polyol ester-based refrigerator oils which are soluble in FC and HFC refrigerants according to DIN 8960. The chemical and thermal stability of these products is excellent.

Legislation passed in 1991 progressively banned the use of CFCs in all refrigeration units. Since January 1995, new equipment must be completely CFC-free. R 134a and R 22 should replace CFC R 12 in the long and short-term respectively. These substitute refrigerants are thus steadily gaining acceptance as is the demand for polyol ester-based, synthetic refrigerator oils. Ester oils are suitable for all refrigerant systems which use R 134a, R 404a, and FC and HFC mixtures. Products with the suitable viscosities (ISO VG 15–220) are available for industrial and household piston and screw compressors. The manufacturers' viscosity recommendations should be observed.

Similarly to all ester oils, saturated and high-purity polyol ester oils can hydrolyze if they come into contact with water in the compressor. It is therefore essential that these products are protected from water, and moisture in general, during storage and use. Ester oils are ultra-dried and are filled into air-tight metal drums with a water content of < 100 ppm in a nitrogen atmosphere [261], [264], [265].

In addition to their properties described in Section 5.3.1.2 polyol esters have the following specific characteristics:

- Excellent solubility in FC and HFC refrigerants
- Avoidance of oil build-up in the condenser/evaporator
- Very good thermal and chemical stability even in the presence of refrigerants
- Compatibility with all commonly-used sealing materials such as NBR, HNBR, EPDM and others
- The products are ultra-dried

Polyalkylene Glycols. Along with the introduction of R 134a refrigerants as a substitute for R 12 in the area of vehicle aircon systems, most of such compressors are designed to use polyalkylene glycol oils. These polyalkylene glycols are not always compatible and miscible with normal lubricants based on mineral oil, alkylbenzenes or esters. Polyalkylene glycols are naturally polar and thus miscible with R 134a. These polar characteristics make polyglycols very hygroscopic and this fact must be taken into consideration when handling these specialized lubricants. When filled, the water content of polyglycol oils should be < 1000 ppm (fresh oil < 500 ppm).

PAG-based refrigerator oils are ultra-dried before use [261].

Fully synthetic, polyglycol-based refrigerator oils (ISO VG 68, ISO VG 100) are also used for ammonia refrigerant systems.

In the past, ammonia system lubricants used relatively naphthenic mineral oils, alkylbenzenes or PAO. The problems of oil enrichment and oil deposits in such systems are well known. Polyalkylene glycols on the other hand, display excellent solubility in ammonia refrigerants. Such good solubility will lead to new system designs in the future including very low temperatures and dry evaporation. The carefully selected synthetic components display excellent $V-T$ behavior and high thermal stability. The water content of polyglycol oils must be kept low (about 300 – 500 ppm). Mixing or contamination with mineral oil must be avoided (formation of reaction products!) [266].

Other Synthetic Fluids. In the past, polysilicic acid, ester-based synthetic fluids were used for evaporation temperatures below – 120 °C. Products based on low-viscosity silicone oils (polydimethylsiloxane; PDMS) are also used.

Refrigerator Oils for CO_2. The natural refrigerant CO_2 is gaining acceptance among users. The properties of CO_2–oil mixtures are not fully known. In principle, the solubility of CO_2 in oil increases in the order

MO > AB > PAG > POE, i.e., at the same temperature and pressure, the most CO_2 is dissolved in ester oils and the least in mineral oils. Depending on the type of oil, carbon dioxide causes varying degrees of viscosity drops. In terms of mass %, viscosity decreases in the order AB > MO > POE > PAG. According to this, the viscosity of polyglycol- based oils fall the least. Suitable CO_2 refrigerator oils are currently being developed. Apart from solubility, thermal stability is also an important factor (outlet temperatures approx. 160 – 180 °C) [267], [268].

10.2.4. Viscosity Selection

The guidelines for the selection of refrigerator compressor lubricants are much the same as those applied to engineering in general, i.e., fast running machines permit the use of lower viscosities than slow running machinery. High bearing loads require higher viscosities than low bearing loads. In addition, refrigerator compressors require much lower viscosities than those calculated from the hydrodynamic lubrication theory.

In the past, many refrigerator systems were operated with chlorinated refrigerants. Chlorine compounds are excellent EP additives which protect against wear. Since the introduction of chlorine-free refrigerants, this function must be performed by the refrigerator oil.

The most important parameter for determining the lubricity of oils or oil – refrigerant mixtures is viscosity.

Mixture Concentration in Relationship to Temperature and Pressure. Figure 53 shows how much refrigerant is dissolved in a refrigerator oil when saturated at a defined operating condition (pressure, temperature). As saturation is time-related, the refrigerant concentration shown by the diagram is, as a rule, greater than the actual value. It can be viewed as the maximum concentration at any given operating condition. The viscosity which can be taken from the mixture concentration adds a safety margin to any bearing loading calculations.

Mixture Viscosity and Density in Relationship to Temperature, Pressure and Refrigerant Concentration. The precise refrigerant concentration in a system is given at a defined pressure and temperature as shown in Figure 53. Figure 54 can be used to read-off the kinematic viscosity of the oil – refrigerant mixture at a defined temperature, defined pressure and defined refrigerant concentration.

Care should be taken that the oil does not reach its maximum viscosity at problematic points in the oil return circuit (e.g., upward flows). It is also important that the conditions in the compressor crankcase do not approach those indicated by the falling left-hand part of the $V-T$ graph because the smallest temperature fluctuations can have a significant effect on viscosity in such conditions [261].

The density of an oil refrigerant mixture depends on the density – temperature behavior of the oil and the refrigerant.

Miscibility Gap, Solubility Threshold. R-refrigerants are among the most oil-soluble refrigerants. However, not all are miscible in refrigerator oils at all temperatures and in all concentrations. If, for example, a fully homogeneous oil – refrigerant mixture is cooled, a point is reached when the mixture separates into two phases. The size of the miscibility gap depends on the type of refrigerant and also to a large extent on the type of refrigerator oil. Refrigerant solubility is defined statically in E DIN 51 514. For normal applications, the miscibility gap (with alkylbenzenes) is not a problem for a series of refrigerants such as R 22. Some other refrigerants display pronounced miscibility thresholds. The miscibility gap is of great importance to the refrigerant circuit. If the oil – refrigerant ratio is within the miscibility gap, problems can occur caused by oil-enriched phases depositing in collectors, condensers, evaporators and the crankcase. Flooded evaporators require the largest possible quantity of refrigerant to be dissolved at evaporating temperatures without the phases separating.

If the turbine oil supplies also a turbine gear set, the oil has to reach a load stage of min. 8 according to DIN 51 345, part 1 and part 2 (FZG).

11. Turbine Oils

11.1. Demands on Turbine Oils – Characteristics

The demands on turbine oils are defined by the turbines themselves and their specific operating conditions. The oil in the lubricating and control circuits of steam and gas turbines has to fulfil the objectives [271], [272]:

- hydrodynamic lubrication of all bearings and the lubrication of gearboxes
- heat dissipation
- functional fluid for control and safety circuits
- avoidance of friction and wear on gear tooth flanks in turbine gearboxes and when the turbine is spooled-up

Apart from these mechanical – dynamic requirements, the following physical – chemical specifications also have to be fulfilled by turbine oils [271], [272]:

aging stability for long operating periods
hydrolytic stability (especially of the additives used)
corrosion protection even if water, steam and/or condensation is present
reliable separation of water vapor
rapid air release and low foaming
good filterability and purity

Annex A (normative) – for EP turbine oils
If the turbine oil supplies also a turbine gear set, the oil has to reach a load stage of min. 8 according to DIN 51 345, part 1 and part 2 (FZG).

These stringent demands on steam and gas turbine oils are met with carefully selected base oils and the inclusion of special additives.

11.2. Formulation

Turbine oils used today contain special paraffinic base oils with good $V-T$ characteristics, antioxidants, and corrosion inhibitors. If geared turbines require a degree of load-bearing capacity (e.g., failure load stage FZG 9 – DIN 51 345), some mild EP additives are included.

These days, turbine base oils are created exclusively by extraction and hydration. Refining and subsequent selective high-pressure hydrogenation significantly determine and influence turbine oil characteristics such as oxidation stability, water separation, air release and foaming. This applies in particular to water separation and air release because these feature cannot be subsequently improved with additives. Steam turbine oils are generally made of special paraffinic base oil cuts [270–272].

A combination of phenolic and aminic antioxidants (synergies) are added to turbine oils to improve their oxidation stability [271]. To improve corrosion protection, non-emulsifiable corrosion protection agents and nonferrous metal passivators are used. These are not negatively affected by water or steam contamination during operation and remain suspended. If

standard turbine oils are used in geared turbines, mild, long life, temperature and oxidation stable EP additives (organophosphorus and/or sulfur compounds) are included. Furthermore, small quantities of silicone-free antifoams and pour point depressants are also used in turbine oils [271–273].

Moreover, these additives must not detrimentally affect the air release (very sensitive) of the oil. All additives should be free of ash (e.g., zinc-free). The purity of a turbine oil according to ISO 4406 should be 15/12 in the tank [274–277]. No circuits, wires, cables or insulation containing silicone should come into contact with turbine oils.

11.3. Specifications

Special paraffinic mineral oils with additives are normally used for gas and steam turbine lubricants. These serve to protect all shaft bearings in the turbine and generator as well as the gearbox in corresponding configurations. They can also be used as hydraulic fluids in control and safety systems. Fire-resistant, synthetic Type HFD-R fluids [272] are normally used in hydraulic systems which operate at pressures around 40 bar, if there are separate lubricating oil and control oil circuits (twin circuit systems).

DIN 51 515 (Lubricants and Control Fluids for Steam Turbines, issued 1986) is presently being revised. Following ISO 6743, Part 5, Family T (Turbines) – Classification of Turbine Oils [278], the latest draft of DIN 51 515, dated 1999, classifies turbine oils as in Table 33.

Table 36. ISO 6743-5 classification of turbine lubricants, Draft 1999

	Normal turbine oils	High-temperature turbine oils
Without EP	ISO-L – TSA (steam) ISO-L – TGA (gas)	ISO-L – TGB (gas)
With EP	ISO-L – TSE (steam) ISO-L – TGE (gas)	??*

* Under discussion.

The demands made by DIN 51 515-1 – Steam Turbine Oils [278] and DIN 51 515-2 – High-Temperature Turbine Oils [278] are shown in Tables 34 and 35.

ISO 6743-5 classifies turbine lubricants according to whether they are used in steam or gas turbines and if they contain EP agents (Table 36) [279], [280].

Synthetic fluids such as PAO and phosphoric acid ester are also listed (see Table 37) [279], [280].

Table 38 [274–277] shows the principal demands made by the world's leading turbine manufacturers. The main differences between these demands relate to the aging and/or oxidation tests.

11.4. Turbine Oil Circuits

The oil circuits play an especially important role in the lubrication of power station turbines. Steam turbines are normally fitted with pressurized oil circuits and separate lubricating and control circuits as well as separate lubricating and control oil tanks are used.

In normal operating conditions, the turbine shaft-driven main oil pump draws oil from the tank into the control and bearing supply circuits. Pressure in control circuits is normally between 10 and 40 bar [269–272]. Oil tank temperatures range from 40 – 60 °C. The velocity of the oil in the feed circuit is about 1.5 – 4.5 m/s [271]. Cooled and passing through reduction valves, the oil reaches the turbine, generator and possible gearbox bearings at a pressure of ca. 1 – 3 bar. The individual oil feeds return to the oil tank at atmospheric pressure. The lubricating oil circuit of a gas turbine is largely similar to that of a steam turbine.

Larger oil circuits are fitted with centrifugal by-pass filtering systems. These ensure that the finest of contaminants are removed along with aging byproducts and sludge.

Oil aging is also influenced by the frequency with which the oil is pumped through the circuit. If the oil is pumped too fast, excessive amounts of air are either dispersed or dissolved (problem: cavitation in bearings, premature aging etc.). Oil tank foaming can also occur but this generally collapses rapidly.

11.5. Monitoring and Maintenance of Turbine Oils

In normal circumstances, oil monitoring intervals of one year are perfectly acceptable. [270],

Table 37. Classification of lubricants for turbines, ISO 6743-5, Draft 1999.

Part 5: Family T (Turbines): Table – Classification of lubricants for turbines				
	General application	Composition and properties	Symbol ISO-L	Typical application
1)	Steam turbines, directly coupled or geared to the load, normal service	Highly refined petroleum oil with rust protection and oxidation stability	TSA	Power generation and industrial drives and their associated control systems, marine drives, where improved load carrying capacity is not required for the gearing
2)	Gas turbines, directly coupled or geared to the load, normal service		TGA	
3)	Steam turbines, directly coupled or geared to the load, high load-carrying capacity	Highly refined petroleum oil with rust protection, oxidation stability and enhanced load carrying capacity	TSE	Power generation and industrial drives and marine geared drives and their associated control systems where the gearing requires improved load-carrying capacity.
4)	Gas turbines, directly coupled or geared to the load, high load-carrying capacity		TGE	
5)	Gas turbines, directly coupled or geared to the load, higher-temperature service	Highly refined petroleum oil with rust protection and improved oxidation stability	TGB	Power generation and industrial drives and their associated control systems where high temperature resistance is required due to hot spot temperatures
6)	Other lubricants a) TSC – Synthetic steam turbine fluids with no specific fire-resistant properties (e.g., PAO) b) TSD – Synthetic steam turbine fluids based on phosphate esters with fire-resistant properties c) TGC – Synthetic gas turbine fluids with no specific fire-resistant properties (e.g., PAO) d) TGD – Synthetic gas turbine fluids based on phosphate esters with fire-resistant properties e) TCD – Synthetic fluids for control systems based on phosphate esters with fire-resistant properties			

[272], [274]. As a rule, these should be performed in the oil manufacturer's laboratories. In addition, a weekly visual inspection of the oil should be performed to spot contamination and impurities in the oil in good time. Filtering the oil with a centrifuge in a by-pass circuit is a reliable method.

11.6. Life of (Steam) Turbine Oils

Oil life of 100 000 h is not uncommon in large steam turbines [270], [271]. However, the antioxidant level in the oil can fall to about 20 – 40 % of the fresh oil (oxidation, aging). The life of turbine oil depends heavily on operating conditions such as temperature and pressure, oil circulation speed, filtering and the quality of maintenance and finally, the amount of oil topped-up (this helps maintain adequate additive levels).

The temperature of the oil in a turbine depends on the bearing loading, speed, bearing dimensions and the oil's flow rate. Radiated heat can also be an important parameter. The oil circulation factor, i.e., the ratio between flow volume per hour and tank volume should be between 8 and $12\,h^{-1}$ [271–273]. Such relatively low oil circulation factors ensure that gaseous, fluid and solid impurities can be efficiently separated while air and other gases can be released. Furthermore, low oil circulation factors reduce the thermal loads on an oil (with mineral oils, oxidation speed doubles when the temperature increases by 8 – 10 K).

11.7. Gas Turbine Oils – Application and Requirements

Gas turbine oils are used in stationary turbines. These produce either electricity or heat. The compressor fans generate pressures of up to 30 bar which vent into the combustion chambers where gas is injected [271]. Depending on the type involved, combustion temperatures of up to 1000 °C are reached (generally 800 – 900 °C) [271], [281]. Exhaust gas temperatures can reach about 400 – 500 °C.

Common mineral oil-based steam turbine oils are used for conventional gas turbines. However, since the temperature of some bearings in gas turbines is higher than in steam turbines, premature oil aging can be expected. Moreover, hot-spots can occur around some turbine bearings and localized temperatures can reach 200 – 280 °C [271] whereby the temperature of the oil in the tank remains at about 70 – 90 °C.

Base Oils:

[a] Mineral oils or synthetic oils with additives to improve corrosion protection and aging stability (additionally EP/AW additives in the case of gearbox lubrication). PAO accepted for steam turbines, PAO not accepted for gas turbines.

[b] Petroleum lubricating oil: Synthetic Hydrocarbons with greater high temperature, oxidation stability and R&O inhibitors, EP/AW additives.

[c] Petroleum lubricating oil: Synthetic Hydrocarbons with greater high temperature, oxidation stability and R&O inhibitors.

[d] Refined mineral oils with aging inhibitors and corrosion protection additives (no EP/AW additives).

Other important specifications (examples):

Westinghouse: I.L. 1250-5312 – Steam Turbines; 21 T 0591 – Gas Turbines; Solar: ES 9-224 – Gas Turbines.

[e] L.S. = Load Stage.

The temperature of the oil reaching a bearing is mostly between 50 – 55 °C and the exit temperature about 70 – 75 °C [271]. The volume of oil for a 40 – 60 MW generator (GE) is about 6000 – 7000 L and its life is between 20 000 and 30 000 h (in the case of a 40 – 60 MW Siemens, 14 000 L and 40 000 – 80 000 h [274], [277]. Semisynthetic turbine oils (multiple hydrated base oils) or fully synthetic turbine oils based on synthetic PAO's are recommended for these applications [271], [272], [276].

In civil and military aviation, gas turbines are used for propulsion. Because of the high temperatures encountered, special, low-viscosity (ISO VG 10, 22) synthetic oils based on saturated esters (e.g., neopolyesters) are used in these aircraft engines or turbines [281]. Aviation turbine oils containing special naphthenic base oils (ISO VG 15 – 32) with good low-temperature characteristics are also used [281].

11.8. Fire-Resistant, Water-Free Fluids for Power Station Applications

For safety reasons, fire-resistant fluids are used in control and governor circuits which are exposed to ignition and fire hazards. In power stations, this applies in particular to hydraulic systems in high temperature zones such as near to superheated steam pipes. The fire-resistant hydraulic fluids used in power stations are generally water-free, synthetic fluids based on phosphoric acid esters (type DFD-R HFD-R according to DIN 51 502 or ISO 6743-0, ISO VG 32–68) and offer the following features [272]:

- fire-resistance
- self-ignition temperature over 500 °C
- auto-oxidation stable to surface temperatures up to 300 °C
- good lubricity
- good protection against corrosion and wear
- good aging stability
- good demulsification
- low foaming
- good air release and low vapor pressure

Additives to improve oxidation stability (possibly foam inhibitors) as well as rust and corrosion inhibitors are sometimes used. According to the 7th Luxembourg Report, the maximum permissible temperature of HFD fluids in hydrodynamic systems is 150 °C. Continuous temperatures of 80 °C should not be exceeded in hydraulic systems. These synthetic fluids are generally used for control circuits, but in some special cases, also for the lubrication of plain bearings in turbines as well as other hydraulic circuits in steam and gas turbine installations. However, these systems must be designed for these fluids (HFDR-compatible elastomers, paint finishes and coatings). DIN 51 518 lists the minimum requirements which power station control circuit fluids have to fulfil. Further information can be found in guidelines and specifications relating to fire-resistant fluids.

11.9. Lubricants for Water Turbines and Hydroelectric Plants

Operators of hydroelectric power stations have to pay particular attention to the handling of water-polluting substances, e.g., the lubricants employed. The specific operating conditions of the hydroelectric plant need to be considered when selecting lubricants. The lubricants must display good water and air release, low foaming, good corrosion protection, FZG Wear protection > 12 in gearboxes, good aging resistance and compatibility with standard elastomers [272]. As there are no established standards for water turbine oils, the existing product specifications for general turbine oils are adopted as basic requirements. The viscosity of water turbine oils depends on the type and design of the turbine as well as its operating temperature and can range from 46 to 460 mm^2/s at 40 °C. Type TD and LTD lubricating and control oils according to DIN 51 515 are used. In most cases, the same oil can be used for bearings, gearboxes and control equipment. In many cases, the viscosity of these turbine and bearing oils is between 68 and 100 mm^2/s. Water turbine oils are subject to little thermal stress, and as oil tank volumes tend to be high, the life of water turbine oils is very long. In hydroelectric power stations, the oil sampling and analysis intervals can be correspondingly long. Particular care should be taken when sealing the turbine's lubricating oil circuit from possible water ingress. In recent years, rapidly biodegradable water turbine oils based on saturated esters have proven successful

in practice. In addition, Type HLP 46 hydraulic oils, Type HEES 46 rapidly biodegradable fluids and NLGI grade 2 and 3 greases are used in hydroelectric plants [272].

12. Metalworking Fluids [51]

The great flexibility and versatility of the different types of machining method are particularly significant in the metalworking industries. Although for some years now there has been a growing trend towards noncutting (forming) methods for workpiece quality reasons and to save material and process costs, this has not led to a recognizable decrease in the volume share of lubricants. This is also apparent from the machine tool statistics. The dramatic change predicted in the 1970s did not take place in the 1980s and 1990s.

Because of the particular significance of cooling for the cutting operation, this process is called cooling lubrication and the fluids used are called coolants. Apart from this term 'coolant' which is commonly used in general practice, there are also numerous other terms for specific applications such as, for example, cutting oils, grinding oils, reaming oils, deep hole drilling oils and honing oils.

The advantages of cutting fluids can be summarized briefly as follows: accelerated heat dissipation with increased tool service life to make higher cutting speeds possible; lubrication between tool, chip and workpiece with reduced tool wear and improvement of the quality of the workpiece surface finish; lubrication of sliding points outside the actual cutting zone between tool, workpiece and chips; and improved chip removal. Frequently less attention is paid to lubrication outside the tool – chip contact zone which, nevertheless, can be very important. Examples are margins of twist drill and reamers as well as the support and guide rails on deep hole drills and honing tools.

12.1. Mechanism of Action

When machining by cutting, a very reactive 'clean' workpiece material surface is continuously generated which can tend to react adhesively on the cutting surface of the tool in the workpiece material – tool contact zone. It must be assumed that this reactive surface not only tries to saturate the free valances of the tool material but that other available substances are also involved which can be bonded by physical or chemical absorption, or chemical bonding. The oxygen in the air plays a particular role. In numerous tests under vacuum it has been established that the tool wear is considerably reduced through the saturation of the surface opened up by cutting, compared to where a gas or gas mixture has been available at different partial pressures.

Coolant penetration into the contact surface [282] is via a network of capillaries which is linked to each other. The width of the capillary diameters is 10^{-3} to 10^{-4} mm.

As far as the saturation process of the newly formed surface is concerned, the surface is never completely covered by lubrication effective molecules; there is a clear gradient of surface activity in the direction of the tool tip, with little reaction at the outer range of the tool. High normal pressure also prevents lubricant transport when machining materials which are difficult to cut. The assessment of cutting tests with model substances has shown that 30 % saturation of the contact surface between chip and tool lead to a reduction in friction force by 75 % [282].

Cooling. In view of the findings relating to cooling and lubrication, it is impossible to differentiate the two. The changes in material properties caused by temperature are closely associated with the effect of friction. Cooling gains increasing significance for tool wear when the maximum cutting temperature approaches the softening point of the tool material.

On the one hand the cooling effect of the cutting fluid and the heat dissipated depends on its thermal properties, especially the heat capacity and the heat transfer coefficient; on the other hand the flow conditions and the heat transfer coefficient play a significant role. The heat transfer coefficient can be influenced considerably by the substances active at the interface and by evaporation.

The high specific heat and high heat transfer coefficient of water give water-miscible cutting fluids more favorable cooling properties than non-water-miscible oils.

12.2. Water-Miscible Cutting Fluids

By volume this is the most significant group of metalworking fluids in the USA and Europe (using as a reference the amount of concentrate from which the users produce the water-mixed finished products). In the Far East, especially in Japan, non-water-miscible products clearly outweigh water-miscible products. Here the trend to increase the share of water-miscible products is even more evident, whereas in Germany, a trend towards non-water-miscible products is more apparent, not least because of the stringent legislation covering storage and handling of lubricants of all kinds.

The question of the cutting performance of water-miscible cutting fluids, which has considerable significance, is not generally of primary importance in their selection, as is the case with non-water-miscible cutting fluids. The secondary demands put on these products are frequently so much the focal point of discussions that their actual main tasks, such as cooling and lubricating, are overshadowed. Of ever-increasing importance are the problems of health protection in the workplace, microbiology, hygiene and the disposal of used fluids.

12.2.1. Composition

The main ingredients of water-miscible can be summarized in the following groups [283].

1) Mineral oil hydrocarbons
2) Synthetic hydrocarbons, synthetic esters, fatty oils
3) Emulsifiers (alkali and alkanolamine soaps, naphthenates, sulfonates, sulfates, ethoxylates, sorbitan estes)
4) Corrosion inhibitors (alkali and alkanolamine soaps, naphthenates, amines, amides, boron compounds)
5) Stabilizers, coupling agents (glycols, alcohols)
6) Extreme pressure additives
7) Antiwear additives
8) Lubricating film improvers
9) Antifoam agents
10) Microbiocides
11) Complexing agents (EDTA derivatives)

Even if mineral oils are the major constituents, then part or even the total mineral oil content can be replaced by synthetic hydrocarbons such as polyalphaolefins or alkyl benzenes by fatty oils or even synthetic esters. In many cases the use of synthetic hydrocarbon is restricted to specific areas of use but synthetic esters or natural fat oils are in regular use.

Basically, suitable water-miscible cutting fluids can be produced both from paraffinic and naphthenic oils; naphthenic oils, however, have a higher solubility for additives and more favorable emulsifying properties. However, the use of naphthenic oils is declining because of their higher aromatic content compared with paraffin ic oils. This is considered critical, particularly with regard to health and safety at work.

12.2.2. Corrosion Protection and Corrosion Test Methods

Normally the corrosion protection afforded by a water-mixed cutting fluid is reduced as the degree of dilution increases. The quality of a product, as far as its corrosion protection properties are concerned, is, therefore, most frequently defined in laboratory application according to the concentration which still gives no corrosion or achieves a specific degree of corrosion. The most significant test methods are described in DIN 51 360, Part 1 (Herbert corrosion test) or IP 125 as well as in DIN 51 360, part 2 (chips/filter paper method). Similar testing methods are known under ASTM D-4627 and IP 287 whereas the French standard NF T 60-188 is more similar to the Herbert test.

12.2.3. Concentration of Water-Mixed Cutting Fluids

The possibility to produce water-mixed products from water-miscible coolants with varying concentrations for adaptation to different cutting processes gives great flexibility. Normally, water-mixed coolants with concentrations up to approx. 30 % can be applied without any particular problems. However, if this concentration range is exceeded then the stability has to be assessed, especially in the case of conventional emulsions. When working with hard water, lime soaps can arise when working far below this

concentration, which could lead to considerable irregularities in the course of machining; this depends to a great extent on the specific composition of the coolants. Often, the lower concentration limit is determined by the corrosion protection properties. In this respect, attention is drawn to the fact that concentrations below 1.5 % can only be checked with difficulty during operation because measurement of the concentration is a problem. Reducing the concentration by only a few tenths of a percentage point can already lead to a serious corrosion effect. In the case of water-miscible coolants, which contain microbiocides, the skin compatibility of these products must be observed when using particularly high concentrations; this also applies for other additives. Normally, cutting fluids are very often used for rough machining with a concentration of between 2 and 5 %, but very frequently at 4 %. In the case of special applications such as deep hole drilling, reaming or generally for particularly difficult cutting operations the use of considerably higher concentrations is possible.

Frequently a concentration of between 1.5 and 2.5 % is selected for grinding operations which are to be carried out with water-mixed coolants. In the case of high performance grinding (grinding with high chip volume) higher concentrations are also sometimes used.

12.2.4. Stability of Coolants

Stability is the most important property for the service life of a coolant. Apart from the general terms for stability, in coolant practice stability is also defined according to the different stresses experienced during service. For example, electrolytic stability, thermal and boiling stability and frequently also stability against microorganisms.

12.2.5. Foaming Properties

In all metalworking sectors as well as in the metal cutting field, the formation of stable foam on the processing fluids is an undesirable phenomenon. Especially coolant containing surfactants, and these include all emulsions, tend, to a greater or lesser extent, to develop surface foam, under appropriate agitation.

To prevent foaming, the selection of a lower foaming coolant is the first of the measures to be taken. Very low foaming products are especially available amongst the more conventional emulsions. One reason for this is that the surfactant molecules (in this case essentially emulsifier molecules and anionic corrosion inhibitors) are mainly bound on the oil – water interface, that is to say to the oil drop, and are not available to be sited on the foam lamellae.

The effect of the most significant group of defoamers for coolants, the silicones, is based on their particularly low surface tension and their insolubility in both oil and water.

12.2.6. Preservation of Coolants with Biocides

Biocides are used to reduce or avoid heavy microbial activity. Biocides should fulfill the following requirements:

- Effectiveness against as many types of microorganisms as possible (broad spectrum effective).
- Fast action: this has particular significance in the case of systems with high drag-out rates; products which act slowly are taken away with the coolant before they become effective.
- Long continuous effect: the biocide should not lose its activity through reaction with other components or contaminants.
- High thermal stability.
- Low influence on pH value of the coolant: different ways of assessing this exist. In many cases an alkaline biocide is desirable. In the case of coolants in use, which have clearly suffered a drop in pH value through microbial attack, it is expedient to use highly alkaline biocides for correcting purposes. Over and above this, alkaline biocides quickly form an essential part of the reserve alkalinity of coolants. A high alkali reserve at pH < 9 is generally favorable.
- Oil solubility: in many cases use in coolant concentrates (water-miscible coolant) is a basic requirement. The biocide is either dissolved or homogeneously dispersed in the concentrate. The use of biocides without solubility in the concentrate is restricted to the treatment of water-mixed coolants.

- No odor nuisance: no odor nuisance in workshops, both with regard to the biocide's own odor and by generation of odor by a reaction with microorganisms or components.
- Good skin compatibility: since biocides are generally based on a reaction with the proteins of the microorganisms, skin proteins are frequently subject to the risk of attack from these biocides. However, risk of dermatitis begins, as a general rule, in concentration ranges above the usual concentrations used in cutting fluids.
- Low toxicity: no toxic effects must occur when the biocides penetrate the body, either through the skin or through inhalation and swallowing of the coolant spray.
- No waste water hazard: biocides enter sewage/waste treatment plants through the waste water from the cutting fluids in such low concentrations that they can be biologically decomposed without the sludge flora being destroyed. The ability of biocides to be decomposed is necessary in biological clarification plants in order to avoid burdening public waters, especially through fish toxicity.
- High economy: the great expense of preservation of coolants mentioned at the beginning requires high economic efficiency in these products. Both the recommended concentration and the concentration applied in practice should be considered when comparing costs. For better practical handling, the dilution of the active substance should be selected by the biocide manufacturers so that the normal concentration used is between 0.1 and 0.2 % in water-mixed coolants.

The most significant groups of substances used as preservatives are:

- Aldehydes (formaldehydes)
- O-Formals
  alcohol + formaldehyde
  (semi formal of benzyl alcohol)
- N-Formals
  amine + formaldehyde (hexahydrotriazines)
  methylbisoxazolidines
  amide + formaldehyde (*N*-methylchloroacetamide)
- Phenolic derivatives (*o*-phenylphenol)
- Isothiazoles (benzoisothiazole)
  chloromethyl, methyl, octylisothiazoles
- Compounds derived from carbon disulfide (sodium-dimethyldithiocarbamate)
- Sodium pyrithione
- IPBC (3-iodine-propinylbutylcarbamate)
- Phenoxyethanol
- Phenoxypropanol

12.3. Neat Cutting Fluids

Neat cutting fluids are mainly products such as honing oils, deep hole drilling oils, grinding oils and broaching oils which are not mixed with water prior to use. Neat cutting fluids have the following advantages over water-miscible fluids: they offer longer tool life and better surface finishes for difficult operations performed at low cutting speeds, the maintenance of the oil is much less complicated and the life of the oil is significantly longer. The contamination of hydraulic and slideway oils with neat oils is less of a problem than with water-miscible products. Moreover, leaks of hydraulic oils and other machine lubricants are easier to cope with if compatible oils are used.

Their principal disadvantage compared to water-miscible fluids is the poorer cooling offered by oils, particularly in high speed cutting operations. An exception is high speed grinding where the superior lubricity of oil reduces the amount of heat generated. Another disadvantage is the combustibility of oils as well as the explosion risks of oil mist and vapor. As the viscosity of oils is higher than water-miscible metalworking fluids, drag-out losses on chips and components are also higher.

12.3.1. Specifications

Neat metalworking oils are classified according to ISO 6743/7, DIN 51 385, or DIN 51 520 on the basis of the additives used (Table 39).

12.3.2. Composition

Most metalworking fluids are based on petroleum hydrocarbons and contain additives to improve lubricity, wear protection and other additives to manipulate secondary characteristics

such as foaming, misting, corrosion protection, dispersion, oxidation stability and flushing. Of the petroleum hydrocarbon base oils, low-aromatic, paraffinic solvent extracted or hydrocracked products are preferred. Recent trends in Germany are heavily focused on ester based fluids.

Apart from sulfurized fatty oils and polysulfides, sulfur – phosphorus compounds and pure phosphorus compounds are often used as EP additives in advanced cutting oils. The use of zinc- and other heavy metal-based additives in cutting oils is declining due to environmental and wastewater considerations. Chlorinated paraffins are still used as universal EP agents throughout the world but combinations of sulfur additives and ester oils are being increasingly used in Germany and Western Europe as substitutes. The reasons for these developments are the considerably higher disposal costs for products containing chlorine in Germany.

Table 39. Classification of neat metalworking oils according to ISO 6743/7, DIN 51 385 or DIN 51 520

	DIN 51385 Code letters	ISO 6743/7 Code letters
Metalworking oils containing mineral oils without antifriction additives or EP agents	SNO	MHA
Metalworking oils containing antifriction additives	SNP	MHB
Metalworking oils containing EP agents, chemically inactive	SNPA	MHC
Metalworking oils containing EP agents, chemically active	SNPB	MHD
Metalworking oils containing antifriction additives and EP agents, chemically inactive	SNPC	MHE
Metalworking oils containing antifriction additives and EP agents, chemically active	SNPD	MHF

12.4. Application

12.4.1. Machining with Geometrically Defined Cutting Edges

Turning produces parts which are round in shape. Cylindrical and conical surfaces are generated from a rough cylindrical blank which rotates about its longitudinal axis and against a cutting tool. Most turning operations use single-point tools. Normally, a tool holder contains an indexable insert with multiple cutting edges. For turning operations, water-mixed metalworking fluids are used only when running automatic lathes; neat oils are often preferred.

Drilling. The most common shape found in a manufactured part is a circular hole, and many of these holes are produced by drilling. Since the chips are formed within the part, the flutes or grooves normally serve two purposes. In addition to providing a conduit for the removal of chips, they also allow the cutting fluid to reach the tool–workpiece interface. Most drills are made from HSS which demands the application of a cutting fluid [284].

Water-mixed metalworking fluids are used where high cooling properties are required. Recent developments show that this operation may be run also with Minimum Quantity Lubrication (MQL) or by using dry cutting technology. Both techniques depend on the material machined and the machine tool designed for this application.

Milling. A variety of milling processes is available where end milling, slab milling, and face milling are included. High metal removal rates are possible since the tools have multiple teeth and each tooth produces a chip. In most applications, the workpiece is fed into a rotating tool. The feed motion usually is perpendicular to the tool axis, and cutting occurs on the circumference of the tool.

When machining cast iron, dry milling has been state-of-the-art for many years. High tensile steels and aluminum alloys are lubricated with water-mixed metalworking fluids but recent developments show that MQL can in some cases provide further advantages from a cost perspective.

Gear Cutting. The most important machining operations are gear hobbing, gear shaping and gear shaving. The different forms of teeth and various types of machines with different tool kinematics very frequently lead to different oil recommendations by the machine tool maker. Nevertheless, in this case the users very clearly want to use one and the same product for several gear cutting applications. Today in large serial automobile gearbox production this has already been generally achieved and all hobbing and generating shaping operations are carried out with just one oil.

As far as tool cooling is concerned, the tool cutting edges only cut for a comparatively short time and sufficient time is available for cooling. As a consequence sufficient cooling is provided by neat cutting oils. Although today water-miscible coolants are available and can achieve good results, the majority of machine tools for hobbing and shaping are not designed for water-miscible products. The latest trends are towards dry machining and the basis for this is coated tools and chip transportation with compressed air.

Oils with viscosities of ca. 40 mm^2/s at 40 °C are particularly suitable for gear shaving with a higher module ($m > 2.5$); recommended for smaller modules are less viscous oils with viscosities between 15 and 25 mm^2/s at 40 °C.

Deep Hole Drilling. Current deep hole drilling techniques, previously employed for the most part only in the armaments industry, have been steadily modified and are now used in the automotive, shipbuilding, aircraft, machine and tool industries, in industrial plant construction, and for hydraulic and pneumatic equipment.

As one of the process parameters, the cutting fluid can make a considerable contribution to increased economic viability, assuming that all other influencing factors have been optimized. Its principal task is to cool and lubricate the cutting edges. Chemically active EP additives incorporated into the cutting fluid and polar effective substances help to reduce wear and friction.

In addition to the actual cooling and lubricating functions, the cutting fluid, which is fed to the tool at high pressure, must also carry away the swarf from the cutting point. The high-pressure supply system requires not only a carefully designed fluid circuit (with a recirculation rate no higher than 6 h^{-1}), but also for products with low foam and in particular low oil-mist characteristics.

Threading and Tapping. Frequently water-miscible lubricants are used in the production of external threads. The focus is clearly on neat cutting oils for tapping where the materials to be cut are difficult or most difficult (material groups 2 and 3, section 1); typical tapping and threading oils of this type are sulfur active oils with viscosities between 15 and 40 mm^2/s at 40 °C; the proportion of polar substances is also important. Tight drill holes and the low pitch of the internal threads call for less viscous oils because of the favorable flushing properties. Here again the risk of cutting edge build-up is great because of the generally low cutting speed, and damage to the cutting edge can result.

Frequently recommended where tapping is carried out and on difficult and most difficult-to-cut materials are thread cutting pastes (sometimes dilutable with water up to 1 : 5) or oils containing solvent. In particular, products with chlorinated hydrocarbons, more especially 1,1,1-trichloroethane as solvent, are easy to apply by brush or in drops. Today for environmental reasons such products have been replaced by low viscosity hydrocarbon solvents and/or other synthetic fluids.

Broaching. Far more than in many other cutting operations the main consideration in broaching is tool wear or tool life. The reason for this is the fact that the broaching tool is a very complicated part and, the tool is manufactured from one single part. The material is predominantly high speed steel; carbide metal as a tool material is only used for gray iron machining. In the case of broaching several teeth engage at the same time and very frequently the chip width is large. Chip removal can be very problematic which then generally also calls for relatively low viscosity oils.

Temperature sensitivity of the broaching tool combined with cutting from the solid workpiece which follows each tooth without any soft initial cut, call for relatively low cutting speeds. In broaching mostly neat cutting oils are used. At very high broaching speeds and high stock removal rates good results are achieved on free machining steels by using water-miscible coolants, more especially EP emulsions and synthetic products free of mineral oil with relatively high concentrations (10 to 35 %); in this case, compared with neat oils, the improvements of the cooling effect and of chip removal are important factors.

12.4.2. Machining with Geometric Non-Defined Cutting Edges

In all abrasives according to DIN 69111 the abrasive grains are bonded with each other to the base

material. The purpose of the bond is to secure the abrasive grains until they become dull and then release them. A differentiation is made between resinoid ceramic and metallic bonds because of the difference in their elasticity, temperature resistance, heat dissipation and dressing capacity. Their resistance to chemicals is particularly important as far as the coolants used are concerned.

Resin bonded grinding wheels are not stable to hydrolysis and can lose their tensile strength when water-mixed coolants are used [285].

Ceramic materials are highly resistant to chemicals and temperature but are brittle and glass-like in character. Metallic bonds are becoming more and more important as far as superabrasives are concerned because of their high resistance to wear.

Grinding Fluids. The grinding process, as a precision machining process, is used frequently for the final stage machining of workpieces. As a result, high demands are set on component accuracy. Particularly significant in this respect is the coolant.

Its first task is to reduce the friction between the abrasive material and surface of the workpiece in the contact zone and, as a result, lower the temperature in the grinding area. It is necessary to reduce the contact zone temperature to increase the tool life of the grinding wheel and prevent the peripheral zones of the workpiece from being affected in any way.

A further task of the coolant is, of course, to prevent thermal damage to either the workpiece or grinding wheel by dissipating the heat generated. Flushing the grinding wheel clean is an important criterion as far as tool life is concerned. Here the viscosity and quality of the base oil as well as the coolant additives play a decisive role.

Whether a water-miscible coolant or a straight oil is suitable for a process also depends, apart from the above-mentioned criteria, on the peripheral system. Here the machine tool equipment plays a particularly decisive role with regards to extraction, sealing, wiring and type of filter system.

Honing Oils. During honing, there is a very large contact zone between tool and workpiece with relatively low pressures. This means that the heat formation is relatively low compared with grinding so that the coolant does not to have to dissipate any great amount of heat.

An important criterion when honing is flushing the honing stone to remove the stock removed material and thus to ensure that the working surface retains its grip and is self sharpening.

As a consequence, very low viscosity oils between 2 and 10 mm^2/s at 40 °C are used when honing. These are applied, as a general rule, at low pressure but at a high flow rate through ring nozzles. To achieve the component accuracy required, the honing oil is kept at a constant temperature by chillers.

Apart from straight oils, water-mixed coolants are also used, especially when honing cylinder liners with diamond honing stones in the automobile industry. Reasons for this are to be found frequently in the process line, because previous machining is generally carried out with water-mixed fluids. This leads to reduced process costs when uniform media are used.

Lapping Oils. Unlike grinding and honing, lapping is a precision finishing process with non-bonded abrasive. In lapping, the workpiece surfaces are machined by the friction between the workpiece surfaces and the appropriate counter surface in the form of a working disc. The stock removal is by means of a lap (grit and liquid) which is applied between the workpiece and lapping wheel surface.

The purpose of lapping oil is to induce homogeneous mixing of the grain. However, lapping powder agglomeration must certainly be avoided. The lapping oil has an important task to perform in the operation, in that it lubricates properly to prevent cold welding between workpiece and working disk. The lubricating film must not be applied too thickly as otherwise hydrodynamics will prevent stock removal.

In the case of lapping oils a distinction is made between the very low viscous oils, which can only maintain the lapping powder in suspension for a short period of time, and the thixotropic, high viscous products, which suspend the lapping powder for days on end. The advantage of low viscous oils is the very good washing behavior, which is reflected in clean surfaces. Due to the lack of carrier capacity for the lapping powders these products are only used

on machines where the lapping medium tank is equipped with an agitator.

12.5. Storage

Whereas neat cutting oils can be stored for a number of years, water-miscible fluids can be stored for between 6 months and maximum 1 year. Water-miscible products should be stored between + 5 °C and + 40 °C. If the ambient storage temperature falls below 0 °C, the concentrate should be stirred (rolling the drum suffices) and warmed before use.

Containers should, preferably, be stored indoors. If drums are stored outdoors, they should be placed horizontally to avoid water and/or moisture seeping past the bung when the drum 'breathes'.

Ideally, cutting fluids should be constantly monitored. Most importantly, solid and liquid impurities such as chips, abrasion residue and tramp oils should be removed by various centrifuges and/or filters because only clean cutting fluids increase efficiency and reduce scrap. The condition of the emulsion in the tanks should be checked at least weekly, better daily. Such measures can significantly increase the life of the cutting fluid.

Water-miscible cutting fluids require much more monitoring than neat oils. Compared to neat cutting fluids, their change intervals are sometimes very short. The maintenance measures required for small tank capacities are often more complex than for larger central systems.

12.6. Environmental Aspects

Maintenance procedures allow cutting fluids to remain in use for long periods of time. Nevertheless, a point can come at which the level of solid and fluid contaminants has reached such a stage that the fluid has to be disposed of and the system refilled with fresh fluid.

This poses no particular problem in the case of neat cutting and grinding oils which may either be regenerated on-site and used for less demanding applications, used as heating oil or commercially disposed of.

The situation is totally different for water-miscible products which, containing an average of 3 % organic compounds, are water-polluting substances and cannot thus be discharged into rivers or water purification plants. In most cases, expensive treatment is thus necessary. The various separation processes available are not always ideal for the different types of cutting fluid in use. Moreover, the evaluation of the water phase remaining after separation depends on not just national legislation but also local waste water regulations.

Among these processes are:

- Electrolyte separation (e.g., salt and acid splitting)
- Splitting of emulsions with adsorbents (e.g., adsorption with amorphous silica and with metal hydroxides)
- Thermal methods (e.g., immersion heating, thin-film evaporation, incineration)
- Ultrafiltration

12.7. New Trends in Coolant Technology

Oil Instead of Emulsion. These days, the 'oil instead of emulsion' trend is seen as an answer to a number of problems. Not only are cost benefits realizable, but environmental, safety-at-work and technical performance of oils are superior. Another major aspect is the almost unlimited life of oils compared to the fluid change cycles of water-miscible fluids (6 weeks for individually-filled machines and 2 – 3 years max. for central systems). As regards pure machining performance, oils can satisfy more than 90 % of all machining operations.

Replacing emulsions with oils offers better lubricity, improved surface finishes and significantly longer tool life. A cost analysis performed in a gearbox plant generated the factor 2 as an average of all machining operations [287].

The only disadvantages of machining with oils are in processes which generate a lot of heat. With a four-fold reduction in cooling, tool and machining problems can occur. Critical operations include the manufacture of carbide drills from solid stock.

To perform these processes with oil, the viscosity has to be reduced to a minimum. This generates the first conflict between technical performance and safety-at-work. The evaporation of conventional oils based on paraffinic solvent

raffinates rises almost exponentially to falling viscosity. At the same time, the flash point decreases. This problem can only be solved by the use of base oils which combine the advantages of a high flash point with low evaporation at very low viscosities.

In response to these requirements, the first cutting oils based on hydrocracked oils with esters appeared at the end of the 1980s with pure ester oils established on the market in the early 1990s.

The trend towards machining with neat oils presented a range of cost-reduction possibilities. One analysis by a leading German machine tool manufacturer showed that an average of seven different lubricants are used in every machine tool. Apart form the leakage problem and the incompatibility of some lubricants, costs are also generated by the stocking of all necessary lubricants. Incorrect application of lubricants or grade confusion can cause considerable damage to machines or even production stoppages.

One possible solution is the introduction of 'multifunctional' products which satisfy a wide range of machining operations at the same time as fulfilling the demands of advanced machine tool lubrication.

A machine tool fluid family contains the same or compatible additives in lubricants of different viscosities.

The advantages are:

- the unavoidable leaks of hydraulic fluids and slideway oils have no negative effect on the cutting fluid
- manufacturing quality remains constant without complex analytical measures
- tramp oils function as cutting fluids and thus do not create additional costs
- higher process reliability, good machining results and reduced tool wear all serve to lower manufacturing costs
- universal application

Minimum Quantity Lubrication. The ever-changing legislation and an ever increasing awareness of the environment have led to a change in the production processes used up to now and especially in the production auxiliaries such as coolants.

The analysis of an automobile manufacturer [288] published early in the 1990s revealed that a considerable proportion of the process costs are caused by the application of metal working fluids. In this respect the costs for coolant concentrates themselves played an insignificant role. The actual costs are caused by system costs, personnel costs for the care and monitoring of materials, the high personnel and investment costs associated with splitting plants associated with water purification systems and last but not least, the costs for disposal.

This has led to much more attention being paid to the difference between dry machining and minimum quantity lubrication (in minimum quantity lubrication the coolant volume flow does not exceed 50 mL/h) [289]. The drastic reduction in the amount of coolants used as a result of these new technologies only offers a considerable potential for savings in process costs. However, dispensing with coolants also means that the primary functions of the coolants such as cooling, lubrication and chip transportation have to be replaced by other suitable technical solutions.

By means of a proportioning device a small amount of coolant spray (max. 50 mL/h) is applied to the machining point. Of all the dosing equipment on the market only two systems have proved successful [290]. The pressure systems have found widespread use, whereby differences can be made in this case between two strategies for preparing the mix.

All minimum quantity coolant systems have one thing in common. The coolant is dispersed into more or less fine drops which reach the machining point as an aerosol. However this causes the first problems with regards to toxicological and workplace hygiene. Although for some years now, in the case of conventional coolant flooding at the workplace, efforts have been made to minimize spray development by new technologies and low emission coolants, sprays are now being intentionally developed for minimum quantity lubrication which are released into the workshop atmosphere.

Today greases and oils as well as esters and fatty alcohols are in use, apart from conventional mineral oils and water-miscible coolants. Since minimum quantity lubrication is a matter of pure total loss lubrication and the coolant is frequently completely dispersed in the working area in the form of vapors and mist, particular attention should be paid to safety aspects. Ester oils and fatty alcohols with additives with

low toxicological values have proved particularly successful in this respect.

Natural oils and fats have the disadvantage of poor oxidative stability. Ester oils and fatty alcohols should be given preference in the case of processes where high heat is developed to avoid residues on workpieces and machines.

13. Forming Lubricants

According to DIN 8582 a distinction between six main groups of manufacturing processes is made: primary shaping, forming, separating, assembling; changing properties of materials and coating. The processes listed under forming (DIN 8583 forming under compressive conditions, DIN 8584 forming under combination of tensile and compressive conditions, DIN 8585 forming under tensile conditions. DIN 8586 forming under bending conditions, DIN 8587 forming under shearing conditions), all refer to noncutting production. Over and above this, forming technology also includes some subdivisions under severing operations (DIN 8588 severing operations, shear cutting) and jointing (DIN 8589 jointing by forming).

Apart from the differentiation according to DIN 8582, in practical applications the area of forming technology is normally divided into sheet-metal forming and extrusion forming. This conventional distinction is based on the fact that unlike extrusion, sheet metal forming workpieces are produced with nearly uniform metal thickness over the complete product. Additionally, extrusion forming uses much higher forces than are required when forming sheet metal [51].

13.1. Sheet Metal Working Lubricants

Sheet metal forming processes have not only gained considerable importance in the thin sheet metal processing sector but significant progress has also been made in materials which in earlier times could not be processed by forming. Especially noteworthy in this respect is the forming of stainless, austenitic and ferritic, sheet metal which initiated great activity in both the development of lubricants and materials for the tools.

During large scale production, for example in the production of parts for vehicle bodies, the greatest expense in development over recent years as far as lubricants are concerned was not for the actual lubrication but for fulfilling new secondary requirements of the lubricant. Advancements in production technologies made it necessary for lubricants to fulfill specific requirements for removability, new application methods, corrosion protection, behavior during sheet metal adhesive bonding, welding, temperature resistance, compatibility with special coatings along with evolving workplace health and safety concerns.

13.1.1. Deep Drawing

During deep drawing, hollow bodies are produced from metal blanks using punches, dies and blank holders. In no other forming operation are the friction and, as a result, the lubricating conditions so complex. In one and the same drawing operation, a particularly low coefficient of friction can be required in one area and a particularly high coefficient of friction in another.

The drawing force in the flange necessary to form the sheet metal is applied by the punch in the base of the cup and transferred from here through the wall into the flange (area C in Fig. 55). This transmission of force calls for the highest possible coefficient of friction on the punch edge: neither the punch nor the sheet metal blank should be lubricated in this area. This friction area requires lubrication in the boundary mode with a high coefficient of friction and antiwear behavior. This is possible with low viscosity drawing oils, polar substances or EP additives. Moreover, in this case the thickness of the lubricant film must not be excessive. It should be somewhere in the range of the sheet metal roughness R_a. A high coefficient of friction along with antiwear performance can also be achieved in some cases by lubricants with a high filler content. These filling materials or solid lubricants should be blunt in structure but not molybdenum disulfide or graphite.

Since the best possible lubrication and lowest coefficient of friction possible are required on the punch in the blank holder area of the sheet metal flange, a compromise frequently has to be made concerning the lubrication. It is often not practicable to lubricate one side of the sheet

Figure 55. Friction areas when deep drawing a cupA) Friction area between sheet metal blank and holder and sheet blank die; B) Friction area between sheet metal blank and the die radius, C) Friction area between sheet metal blank and the punch edges1) Punch; 2) Blank holder; 3) Die; 4) Cup; 5) Flange area; 6) Cup wall; 7) Base of the cupF_{ges} = Total drawing force; F_N = Blank holder force

differently from the other, especially with small drawn parts.

The cup bottom and the connection to the wall have the least yield during deep drawing. The yield increases with frame height and, as a consequence, also the yield strength. If the drawing force transferred from the base of the cup is too high the sheet metal will tear at the point with the lowest strength resulting in bottom tearing, the most significant and most difficult deep drawing fault to be analyzed [291]. Here, the lubricant has the important task of reducing the considerable frictional component of the total drawing force in the region of the blank holder and the die radius.

The friction situation in the deformation area is explained by studying the friction in the region of the blank holder and the die radius (areas A and B in Fig. 55).

As a result of the tangential pressure stresses and radial tensile stresses in the flange, there is a tendency towards material compression on the outer rim. Because of this thickening of the sheet metal the blank holder can only transfer the blank holder force to a limited section of the sheet surface on the blank holder side, which leads to high surface pressures and difficult friction conditions. As a result of the lack of contact by the blank holder in the other areas, there is also the risk of fold or wrinkle formation. This wrinkling also creates special friction conditions since the backs of the wrinkles cause more or less line contact with the blank holder, producing local areas of high surface pressure.

However, in the case of high viscosity oils and drawing pastes, if the lubricant film applied is excessive, there is the risk that hydrostatic effects on the blank holder side of the flange can cause reduction of sheet metal contact with the blank holder resulting in wrinkling.

The friction conditions on the die are less complex than in the blank holder area. Here the surface pressure can be relatively accurately estimated and the coefficient of friction determined in deflection strip drawing tests. In this case the aim of lubrication is to achieve a minimum coefficient of friction with minimum wear. Even excessive lubrication of the sheet metal surface on the die side normally does not create a problem.

The geometrical design of the die has a significant influence on friction. If very small die radii are necessary for technical reasons, EP lubricants have proven to have a positive influence on the workpiece surface quality as well as die wear in spite of the high surface pressures occuring. However, this does not seem to bring about a reduction of the drawing force.

13.1.2. Stretch Drawing and a Combination of Stretch and Deep Drawing

In stretch drawing the blank sheet metal clamped firmly on both sides is stretched by tensile stress, generally by means of an upwards traveling stretch drawing punch. Here the thickness of the sheet metal is reduced unlike during deep drawing where the thickness of the sheet metal remains mostly unchanged. The goal is uniform deformation which is favored by the lowest possible friction over the entire stretch area. The reduction in sheet metal thickness leads to a considerable increase in surface area which has to be taken into consideration when choosing the type and amount of lubricant to be applied.

13.1.3. Shear Cutting

According to DIN 8580 shear cutting is a severing process in the separating group. Whereas *stamping* is a relatively old method of sheet metal working, *fineblanking* has gained particular significance in the last two decades. Lubrication has a greater significance in fineblanking than in normal stamping as far as the quality of the workpiece and tool wear are concerned. This normally requires higher performing lubricants.

Stamping. A significant characterization of stamping is that one third of the sheet metal thickness is a sheared edge and about two thirds a torn zone. An important stamping method is, for example, making holes for the production of pierced plate for protective grids and for many decorative applications or for the production of screens and filters. The sheared area of stamped parts is subdivided into three areas; the forming area, the cut area and torn area.

Efforts are being made to reduce the number of lubricants used for stamping. This reduction in types of lubricant also makes it necessary for the plants to select lubricants based on the most difficult operations, materials and sheet metal thicknesses. Today the majority of companies try to make due with a maximum of three lubricants in the production of stamped parts by combining blanking and forming operations.

The lubricants used for stamping are divided into 7 or 9 groups and can be described as follows:

- Group 1: oils, 50 to 180 mm^2/s, 40 °C; the oils are either completely or to a considerable extent active substances. Used as substances are EP materials (containing chlorine, sulfur and phosphorus), polar substances (P) such as synthetic esters, natural fatty oils or fatty oil derivatives. Group 1 is designated EP+++P+++.
- Group 2: oils, 30 to 110 mm^2/s, 40 °C; designation EP++P++.
- Group 3: oils, 30 to 110 mm^2/s, 40 °C; the oils are either completely or to a considerable extent polar substances, designation P+++.
- Group 4: oils, 30 to 110 mm^2/s, 40 °C; apart from considerable proportions of polar substances the oils contain lower concentrations of EP substances, designation EP+P+++.
- Group 5a: oils, 15 to 110 mm^2/s, 40 °C; the oils are mixtures of polar substances with mineral oil hydrocarbons, designation P++.
- Group 5b: oil, < 15 mm^2/s, 40 °C; these oils are mixtures of polar substances with mineral oil hydrocarbons, designation P+.
- Group 6a: water-miscible compounds. Mainly, these are products with a grease consistency, possibly also water-miscible oils with considerable concentrations of polar substances and medium to low EP levels, designation EP+P+++. The products are used as undiluted pastes or diluted as lean as 25 %. They are frequently diluted to a ratio of 1 : 3.
- Group 6b: water-miscible compounds. These are simple products without specific combinations of active substances. The products are used undiluted to 15 % but are frequently diluted with water at a ratio of 1 : 5.
- Group 7: corrosion protection oil. This is a surface protection oil which is already applied by sheet metal producers and is also to serve as a lubricant for further processing (mill oils, slushing oils, prelubes).

Most lubricants in Groups 1 to 5 may be diluted with petroleum hydrocarbon solvents. The solvent serves mainly to facilitate application. The difficult-to-cut austenitic materials with a sheet thickness up to 1.5 mm require a lubricant from Group 2 and lubricants for thicker sheet metals are in Group 1. Ferritic CrNi sheet metals require lubricants in Group 2 and for thick-

nesses in excess of 8 mm lubricants in Group 1 are selected. Depending upon thickness, the lubricants in the Groups 4, 2 or 1 are required for carbon steels. Lubricants in Group 5b are suitable for electrical quality sheet whereas the lubricants in Groups 3 to 5b are used for aluminum, non-ferritic metals and their alloys.

Fineblanking. The most significant difference between a part produced by stamping and a part produced by fineblanking is in the quality of the cut surface, which in many applications serves as gearwheels. Significantly higher shape accuracy is achieved by, among other things, a very small die clearance, which in fineblanking is typically only approx. 0.5 % of the sheet thickness. In stamping this clearance is approx. 10 to 15 % of the sheet thickness. The cutting surfaces have no fracture area and the workpieces have only an insignificant burr.

When fineblanking, unlike stamping, the sheet is clamped on all sides by a vee-ring. The specific tool structure is significant for lubrication. Lubricating chambers are formed by special chamfering on parts of the tool [292].

In fineblanking, in general, oils with higher concentrations of additives and oils with reactive EP substances are used because there is a strong tendency towards adhesive wear when fineblanking difficult-to-cut, thick materials with unfavorable structure. Oils with a high chlorine content are frequently used for difficult fineblanking operations [292].

Working with reactive EP substances, especially chlorine compounds, can lead to considerable corrosion problems on fineblanked parts, particularly on the cut surface. Because chlorine compounds cause environmental problems there is a clear trend towards chlorine-free products. The extensive use is of chlorine-free products is already well established in the area of low and medium thickness sheet metal.

Table 40. Different types of sheet-metal-forming lubricant

Lubricants	Main applications	Remarks
Neat lubricants		
Vanishing oils	stamping, drawing, pressing deep drawing of thin sheet metal punching and calibration	flash point 40 – 65 °C
Oils containing polar additives	lamella and disk plate stamping	low viscous applications some lubricants mineral oil free, biodegradable, compatible with prelubes
	embossing, stamping, drawing, pressing car body manufacturing, deep drawing	
Oils containing EP-additives (chlorine free)	severe stamping, pressing, deep drawing fineblanking drawing and ironing	lubricants can cause copper staining
Oils containing EP-additives (chlorine containing)	severe stamping, pressing, deep drawing	high carbon steel, stainless steel, some lubricants do not cause copper corrosion
	fine blanking drawing and ironing	
Drawing compounds without solid matter additives	severe drawing, deep drawing	low to high carbon steel
Drawing compounds containing solid matter and/or EP-additives	most difficult drawing, deep drawing	mostly pasty lubricants
Watermiscible lubricants		
Oils	drawing emulsions or solutions	synthetic, semisynthetic or conventional formulated lubricants
	secondary hydraulic fluid for hydroforming	
Drawing compounds without solid lubricants	severe drawing, deep drawing	sometimes pasty lubricants
Drawing compounds containing solid lubricants	most difficult drawing, deep drawing	often pasty lubricants

13.1.4. Choice of Lubricants

Before Forming. In this field of application a great number of different lubricants are available.

Table 40 shows different types of forming lubricants and their preferred applications.

After Forming. As mentioned before, steel sheet metal and strip are generally provided with a film of corrosion protective or prelube oil in the steel rolling mill. The range of products have not only proved successful as corrosion protective oil but also for the further processing in light to

medium severity drawing operations without an additional lubricant having to be applied.

The remaining film on the parts drawn in this way provides good corrosion protection.

If an additional lubricant (spot lubricant) is applied for forming this can be left in many cases on the workpiece after the operation to provide corrosion protection during intermediate storage or before further processing. However, in the majority of cases, it will be necessary to remove the lubricants immediately after processing or intermediate storage. This is done either by washing or, in the case of heat treatment, during the annealing operation wihtout previous cleaning.

13.1.5. Sheet Metal Forming in Automobile Manufacturing

The pressing of car body parts is one of the most important sheet metal drawing processes. The corrosion protection oil applied by the steel mills plays a part in every sheet metal forming operation and also makes up the largest proportion of lubricants used.

Prelubes. The idea to combine the corrosion protection properties of a corrosion preventive oil with the lubricity of a drawing oil led to the development of the prelubes. Prelubes have existed on the American market for more than 20 years, they were introduced in Europe in the early 1990s. Applied at the finishing lines of the steel mills, they serve as the forming lubricant in the press shops. The use of prelubes in steel mills reduces the number and quantity of spot lubricants for additional press shop oiling dramatically.

Among the many specifications for mill oils, the comprehensive standard of the Association of German Automobile Manufacturers (VDA) [293], [294] describes all relevant requirements of a mill-applied lubricant, defines all important properties and lists all test procedures.

Skin Passing. To achieve the desired quality, the final surface finish of sheet steel is often rolled-on wet. Water-based solutions are normally used for plain cold rolled steel but low-viscosity oils are used for zinc-coated sheet including electro-galvanized or hot dip galvanized. As a result of the increasing use of coated sheet steel in recent years, the compatibility of skin-pass oils is becoming an increasingly important factor. If the skin-pass and the subsequently applied corrosion protection oil are not compatible, the oil film can rapidly separate.

Additional Lubrication. Many drawing operations require additional spot lubrication which is applied in the press shop. These higher viscosity drawing lubricants lose out when prelubes are applied. Ultimately, they will become unnecessary if the lubricity of the mill applied oil on the panels is adequate. If in spite of the prelube, difficult deep drawing still requires the use of additional spot lubricants at critical points, these must be process-compatible. As such spot lubricants are again applied on top of the other oil layers, a thixotropic formulation is also advisable to avoid run-off.

13.2. Lubricants for Wire, Tube, and Profile Drawing

According to DIN 8584 these processes are classified under the manufacturing processes with forming under a combination of tensile and compressive conditions. Wire and rod drawing is applied to produce semifinished products with smooth surfaces and close tolerances for the most varied application purposes. Solid or hollow bodies are generally drawn through a stationary drawing tool (drawing die, drawing nozzle, drawing ring) to reduce the cross section or change the cross section geometrically.

13.2.1. Wire Drawing

In no other forming process the lubrication, the machine and tool technology are so closely associated with each other as in the case of wire drawing. Three different types of lubrication technology are applied:

- *Dry drawing*: (in wire drawing this term does not mean the absence of lubricant but the use of solid, not liquid lubricants) with dry drawing soaps in the drawing box. These lubricants only lubricate the drawing die and hardly ever have a cooling function.

– *Lubricated drawing with pasty or high viscosity lubricants*: which means drawing greases, drawing oils or drawing emulsions.
– *Wet drawing*: Wet drawing is generally done with oil-in-water emulsions, seldom with non-water-miscible oils, however, quite recently, also with special, highly viscous, degradable ester oils.

In wet drawing the task of the lubricant is to lubricate and cool the drawing tools and keep the machines clean. A further criterion for lubricant selection is the thickness of the wire.

Lubricants for Copper Wire Drawing. Water-mixed lubricants are used exclusively. Just in the first draft of coarse wire, a special lubricant of high viscosity is frequently used in the lubricated drawing or, alternatively, the concentrate used in a following wet drawing is used in a predrawing block to ensure more favorable lubricating conditions at the given low drawing speed. The lubricant used for this application must be compatible with the lubricant used afterwards.

Emulsions are the most important of all the lubricants in wet drawing. Apart from these, surfactant solutions, free of mineral oil and fatty oil, are significant. To a small extent other synthetic solutions are also used. The three groups of lubricants (see Table 41) can be characterized on the basis of the most important ingredients.

Table 41. Lubricants for wet drawing copper wire

Type of lubricant	Ingredients
Emulsions	hydrocarbons, mineral oil
	natural fatty oils
	synthetic esters
	nonionic surfactants
	anionic surfactants
	stabilizers, inhibitors
	antifoam agents
	other additives
Surfactant solutions	alkali soaps
	alkali salt of sulfated fatty oils
	nonionic surfactants
	other additives
Other synthetic solutions	polymers
	organic salts
	inorganic salts
	other additives

In practice these differ mainly through their degree of dispersion or their solubility properties in water.

The emulsions can vary from relatively coarsely dispersed emulsions with an average drop size of approx. 5 µm to the finely dispersed emulsions of an average drop size under 1 µm.

Lubricants for Steel Wire Drawing. The same basic technical requirements apply for wet drawing as is the case for copper wire drawing. The thicker the wire is for drawing, the greater the need for effective lubricating polar and EP substances. This applies for the emulsions used in the fine wire sector as well as for the drawing oil in the medium wire section.

Occasionally pasty drawing greases containing fillers are used in the lubricated drawing before wet drawing. The combination of semiplastic lubricant carrier layers with circulating oil lubrication is also a type of lubricated drawing [295]. However, the major portion of steel wire in coarse and medium draft is drawn with dry drawing soaps.

Dry drawing soaps are composed of alkali, alkaline-earth, and group 13 metallic soaps, sodium, calcium, and aluminum soaps are the most important. The soap content of the stearates can be between 20 to 80 %. Used as further substances in the content are natural and synthetic (under certain circumstances also chlorinated) waxes, polymers, inorganic solid substances such as lime, borax, soda, talcum, titanium oxide as well as molybdenum disulfide, graphite and sulfur. Generally alkaline-earth and group 13 metallic soaps are not dissolvable in water, but on the other hand sodium soaps are very soluble in water. This is why alkali stearates can be also applied by immersing the wire coil in the hot aqueous soap solution with subsequent drying, besides being used in the drawing box.

Dry drawing at high speed calls for lubricants with high melting soaps due to the high development of local heat. Generally, stearates have a higher melting point than oleates.

Nevertheless, technical drawing soaps are not only selected according to their melting point. More important are generally the lubricating properties, the matching grain size distribution, the flowability in the drawing box, the protection against wear for the drawing dies, the further processing of the semifinished products and the corrosion protection, etc.

In practice, it is the grain distribution and flowability of the dry drawing soap which are

decisive for lubrication. Coarse grains flow better than fine grains but are not so easily picked up by the wire. The degree can be determined by screen analysis. The resistance of a drawing soap to abrasion is also important. It depends upon the composition, production process and the milling and must not be too high so that the wire can take enough lubricant with it.

Lubricants for Aluminum Wire Drawing. To some extent, drawing compounds with a high content of drawing effective (polar) substances are still found in the non-slip single draft. Otherwise almost only very age-stable non-water drawing oils in a wide range of viscosities are used. For drawing coarse wire the oil viscosities can be between 300 and 1000 mm^2/s at 40 °C, in medium wire drawing between 50 and 100 mm^2/s and in finest and super-finest wire drawing oils with very low viscosity are frequently used, for example, 2 to 10 mm^2/s at 20 °C. The higher the viscosity, the more important preheating the oil becomes at start-up.

In the case of aluminum wire drawing very fine abrasion particles occur. Normal oil filtration, as it is used in other applications, faces great difficulties in the case of aluminum wire drawing so that the particles can normally only be removed by sedimentation at stand-still. Altogether in this way very long oil service lives (as a general rule several years) are achieved.

Lubricants for Wire Drawing from Other Materials.

Stainless Steel. For wire drawing of stainless steel, oxalate coating and also plastic films, for example from chlorinated polymers or lead layers are applied as a lubricant carrier. Lubrication in the drawing dies can be provided by dry drawing soaps or with EP oils (highly additivated, generally containing chlorine) [295].

Medium and fine wire is drawn with EP oils, finest wire also with water-miscible lubricants.

Nickel behaves in a similar way to stainless steel. Coarse wire with sodium stearate is drawn with non-water-miscible EP oils, which must be free of corrosive sulfur. During the annealing (> 800 °C in reducing atmospheres) the lubricant residue must not have a detrimental effect on the nickel surface.

Tungsten wire, which is required for the production of incandescent bulbs, is produced by a special method (→ Lamps, Chap. 5.1.). Aqueous dispersions of colloidal graphite [296] are used as lubricants. In the case of tungsten wire drawing the oxide layer serves as a lubricant carrier and improves the adhesion of the graphite [297], [298].

13.2.2. Profile Drawing

In the case of wire and rod drawing the preliminary materials will normally have a circular cross section. Where profile drawing is concerned, an extrusion molded, generally hot rolled initial material is available which already has a similar profile to that of the finished material.

Profile drawing is dominant in all kinds of steel working but has much less significance by volume in nonferrous metals.

The profiles are drawn on drawing benches, to some extent at > 150 m/min, with drawing carriages which are moved by chains, ropes, toothed racks or hydraulic plungers.

Lubricants for Profile Drawing. Dry drawing soaps in drawing boxes or even water soluble drawing soaps (applied by immersing the preliminary material in sodium stearate solution, for example) are used for lubrication. However, oil circulation lubrication has the greatest significance for completely flooding the intake side of the drawing tool – not least because of the easier insertion of the workpiece in the drawing hole during discontinuous working. The drawing oils usually have a viscosity between 50 and 120 mm^2/s.

Drawing oils with a high percentage of additives are used depending upon the degree of difficulty. In this case the same selection criteria are valid as in the case of wire drawing. Drawing oils containing chlorine are generally removed before intermediate annealing because of the development of corrosive gases. Special emulsions containing solid film lubricants and drawing grease are suitable for particularly polished drawn surfaces.

13.2.3. Tube Drawing

The great significance of tube drawing becomes clear when taking into account that about one

seventh of the steel produced worldwide is used for the production of seamless or welded tube. Moreover, the production of tube made of stainless steel, titanium, aluminum, and especially of copper has considerable significance, both commercially and technically.

Wherever possible, tube is produced by casting or forming methods in the required dimensions and tube quality. Precision tube with defined, closer tolerances, especially with defined surface finishes, can only be produced by cold forming. Cold drawing of tube, apart from other cold forming methods such as cold pilger rolling or cold rolling, is the last link in the production chain. As is the case with profile drawing, tube drawing is performed out on drawing benches. Long lengths of tube, especially copper tube, are drawn on drum drawing machines which in principle work in the same way as single wire drawing machines.

With regards to the tribological demands, the drawing method is the primary factor [299]. in the case of hollow drawing without an inner tool, only external friction occurs and as a result only lubrication from the outside is necessary. In the case of various mandrel drawing processes a considerable improvement in the inner surface finish and a defined wall thickness are achieved with a cross section reduction per draft of up to 50 %.

Lubricants for Drawing of Steel Pipes. Wet drawing with EP oils does play a role for less difficult forming operations, as is the case with profile drawing to produce blank drawing.

A special form of wet drawing is carried out with so-called reactive forming lubricants. These oils contain organic and inorganic derivatives of phosphoric acid applied initially in a heated immersion bath. For example, bundles of tubes are immersed after pickling or inert gas annealing for some 10 to 15 min in heated reactive oil at 40 to 70 °C where they are left a certain period of time before being drawn with the residual oil film. The phosphate layer remains as a rule on the pipes. Although the ferrous phosphate coating produced in this way cannot be stressed to the same degree, tribologically, as zinc phosphate coatings, or even saponified zinc phosphate coatings, the method has gained very strongly in importance for cost reasons. High alloyed materials as specified for rod and profile drawing are drawn with special highly viscous oils with chlorine additive (300 to 1000 mm^2/s, with a Cl content from 30 to 70 %). In this case the inner lubrication frequently turns out to be a problem. Apart from these, certain polymer and cellulose ether films have proved to be suitable.

Emulsion and water-mixed drawing greases have only certain significance when blank drawing with a low degree of deformation.

Lubricants for Drawing of Titanium Tubes. These are important as capillary tubes and for pipeline construction in the aircraft industry. Lubricants containing chlorine have good drawing properties which, however, cannot be used for applications in aircraft construction because of the risk of crack corrosion. The suitability of titanium for phosphatizing is considerably less than that of steel. Tribologically effective coating calls for multistage treatment with acid. In this case there is a risk of hydrogen embrittlement.

Lubricants for Drawing of Aluminum Tubes. The same working principles apply as for drawing aluminum wire. Strong polar forming oils are used mainly for this.

Lubricants for Drawing of Copper Tubes. Copper tube has gained outstanding significance in the refrigeration and air conditioning installation branch. Particularly rational drum drawing machines with high drawing speeds (up to 35 mm/s) are used with flying mandrels. The required quantity of lubricant is supplied by means of grease filler for inner lubricating. Oil circulation lubrication is used for the outside, if necessary, also with emulsions (frequently 30 to 40 %).

13.2.4. Hydroforming

The full name of 'internal high pressure forming' commonly is replaced by the term 'hydroforming'.

First applications using internal pressure are known since more than 100 years for the bending of tubes. In the 1960s the production of T-fittings became a typical application. Then exhaust components, motor cradles and other structural components for automobiles were manufactured. In

the past ten years the hydroforming technology grew considerably and it will gain more and more in importance. This is due to the general demands in saving energy and raw material cost, improved mechanical equipment and process control, replacement of complex structural components manufactured in short process chains (often with additional operations integrated in the hydroforming tools) and to the contributions of an intensive research [300].

Hydroforming is regularly made on tubular components where straight or preformed preproducts are expanded in a split tool by applying hydrostatic pressure [301]. The stages of this operation are as follows. The workpiece is placed into the die, the die halves close, the mandrels (rams or sealing plungers) move in a close position to the workpiece and the pressure fluid is filled into the workpiece while air escapes. The mandrels now seal perfectly and the internal high pressure is built up. The pressure increases and the workpiece is shifted and formed in axial and/or radial direction. Finally when the workpiece is already very close to the shape of the dies a calibration pressure of about 2000 to 2500 bar is applied by which the workpiece is accurately adapted to the contours of the dies.

Lubricants for Hydroforming. Lubricants are used in operations before hydroforming, e.g. for the bending of the tube and the preforming of the workpiece. The remaining lubricant sometimes suits also for the hydroforming process itself. Additional lubrication (sometimes called 'external lubrication') is necessary in many other cases depending on the shape and the geometry of the workpiece, especially when little radii of curvature and difficult formable materials have to be processed. Thus the range of lubricants is wide but intricate. It includes drawing oils and compounds as well as wax films and solid film lubricants [302]. In respect to the pressure conditions lubricants of high polarity in combination with antiwear or EP additives have to be used. The selection is preferably done in accordance with the application conditions. It is clear that the removability of the residues of the lubricant becomes more and more essential since this is the relevant parameter of the general process compatibility.

Another essential parameter is the secondary hydraulic fluid. This functional fluid is the pressure medium in hydroforming while the primary hydraulic fluid is used in bed and slide and to move the sealing plungers as well as the counterpressure cylinders. As secondary hydraulic fluids aqueous solutions or emulsions are in use. The solubility of the hydroforming lubricant in the secondary hydraulic fluid is one of the fundamental features of the hydroforming process.

Where oils are used as external lubricants two alternatives were successfully established in the practice depending both on the constructive conditions of the tank-side equipment and the degreasing facilities after hydroforming: the use of rather soluble and more often the use of insoluble (demulsifying) lubricants.

Additional operating steps are necessary when solid film lubricants are used. The particular application properties of this type of lubricants and the subsequent degreasing possibilities must be adequately arranged.

13.3. Lubricants for Rolling

Based on the quantitative production of semifinished goods, rolling is one of the most significant processes in forming technology. Cast slabs, blooms, billets, and wire can be processed to semifinished products through rolling.

The main forming takes place in the hot-forming temperature range, to exploit firstly, the advantages of lower rolling forces and, secondly, to obtain semifinished products with soft structures suitable for further processing. Semi-hot forming has only been used to an insignificant degree in the rolling sector. In contrast, cold rolling is a process with surprising significance, more especially in view of the increasing demands being put on forming accuracy and the quality of the surface finish.

Of all the products manufactured by rolling, in type and quantity the flat products have the greatest significance, in both the hot and cold rolling sectors. These processes are followed by the important hot rolling processes for tube, section and wire production and the cold rolling process for producing taps and spiral drills. Apart from this, teeth and thread are rolled – even on one-off work pieces – and there are a number of smooth rolling methods for surface finishing. Sheet and strip is made up to $> 90\,\%$ from ferrous metals, aluminum sheet accounts for only

approx. 5 to 8 %, with copper materials in the region of 2 to 3 %.

Wherever possible today, hot rolled strip is used instead of cold rolled sheet because of the lower price.

The use of high quality hot rolling oils in the forming process instead of water cooling has contributed to a large degree to improving the surface quality and the formability of hot strip.

In the past years a continuous further development of lubricants has occurred. Although the lubricants for the various processes are fundamentally different they have many common features for the technology and tribology of rolls, especially for the behavior of the lubricant in the roll gap.

Up to the 1930s, the standard roll stand for the cold rolling of sheet metal was the four-high reversing roll-stand. This was followed by the building of tandem roll stands, in the initial stages predominately three four-high roll stands, followed by four four-high roll stands in the 1950s and, finally, from the 1960s onwards five and six four-high roll tandem lines [303].

Today's five or six-stand tandems run at 1500 to 2000 m/min. Above all, modern roll stands can be run in all working phases at a higher speed with high mechanical safety. The reason for this is the enormous progress made in measuring, testing and control technology.

Unlike other forming processes the friction between tool (work roll) and workpiece (rolled material) when rolling must be neither too high nor too low, so that the friction necessary for feeding can be applied.

Figure 56 shows the rolling process as a simple model. The sheet to be rolled runs at the speed v_1 into the roll gap of the rolls turning at a peripheral speed v_3. During this operation the thickness of the sheet is reduced from s_1 to s_2.

Reducing the roll gap leads mainly to an extension of the rolling stock length but not to an increase in width. Accordingly, the initial speed of the sheet must be lower, and the final speed higher, than the peripheral speed of the rolls. As a result sliding friction occurs. The difference in speed between v_1 (run-in) and v_3 (rolls) given as a percentage, is called backward slip, and the difference between v_2 (run-out) and v_3 (rolls) is called forward slip.

In the contact area of the friction arc there is a point in which the speed of the rolls and sheet is the same, the neutral point N (no-slip point), at which there is no slip. As a result of varying friction, for example, caused by different lubrication, the N position within the friction arc can be moved. By improving the lubrication, N can be moved towards the roll gap exit. It is possible to reduce the pressure tension through an analog-running tensile stress, namely by involving reel tension. The tribological ratios are improved in general through this measure, which increases the degree of deformation efficiency so that the undesirable widening of the strip can be almost completely avoided.

Lower friction has the effect of lower roll wear and prevents the occurrence of heat stripes and similar rolling faults. However, the rolling operation is only possible with a minimum of friction, to safely avoid firstly, so-called refusals when starting the rolling operation, and secondly, to prevent roll slipping (and, as a result, further rolling faults such as, for example, uneven surface roughness, rubble marks, etc.) during the rolling operation.

13.3.1. Rolling Steel Sheet

Hot Rolling. Slab produced by means of continuous casting or continuous casting are produced on hot roll stands. Special hot rolling oils are used in the production of high quality strip on hot wide band lines.

These lubricants comprise thermally stable basic materials and are different from the usual emulsified rolling oils for cold rolling in that they cannot be mixed with water. Hot rolling oils are generally, together with the necessary cooling water, applied to the work rolls by means of a separate spray system and reduce the friction between work rolls and roll bite but also between work and back-up rolls. In this way the tribological relationships are improved in the long-term and lead, more especially, to reduced roll wear. Parallel to this, an effective reduction in thickness can be achieved by lowering the rolling force, in other words, the forming performance increases despite lower consumption of drive energy.

The most significant reason for the use of hot rolling oils is, however, the improved quality of the surface finish down the entire length of the strip.

Figure 56. Principle of the rolling processv_1 is the initial and v_2 the final speed of the sheet, v_3 is the peripheral speed of the sheet, s_1 is the initial sheet metal thickness and s_2 the sheet metal thickness after rolling.

Hot rolling oils contain, besides mineral basic oils, polar and EP active substances, which form a wear-resistant 'protective skin' on the work rolls. The consumption of hot rolling oil for steel is between 15 and 80 g/t.

Cold Rolling. The final thicknesses, which are frequently between approx. 1.1 and 0.4 mm put highest demands on the cooling oil emulsions, particularly in this sector. The rolled strip widths are between 600 and 1800 mm.

The rolling speeds are between 600 to 2000 m/min, depending upon the design of the tandem line, and even higher in individual cases.

Rolling Emulsions. In rolling, the emulsion has to take over the very important function of heat transfer apart from its tribological task. The composition of this lubricant for rolling depends to a great extent on the circulation system and the other conditions and parameters for the rolling operation.

Rolling oil bases are mineral oil hydrocarbon substances or synthetic hydrocarbon material in combination with polar and EP active substances and more especially, a specifically matched emulsifier system. Rolling oil saponification numbers for rolling sheet are frequently between 30 and 130 mg KOH/g, which is equivalent to 15 to 65 % fat oil or ester components. Different synthetic esters are used, frequently polyol esters, but also vegetable and animal fats [304].

Free fatty acids indeed increase the lubricating effect but they must not be too high in proportion because of possible reaction with soluble soaps. The hydrolysis resistance of ester components must be high in order to keep the development of soaps low. The acid value (or neutralization number) of rolling emulsions is about 3 mg KOH/g, equivalent to approx. 1.5 % acids.

Rolling emulsions are mixed with fully softened water, generally between 1 and 3 %. The emulsion temperature is frequently between 35 and 55 °C. The consumption of precoat oil and emulsion concentrate is together between 0.25 and 1.00 kg/t sheet.

The emulsion stability is important for the rolling process. Stabile emulsions are generally used in high volume circulating systems, and metastable emulsions in smaller circulating systems. In the case of metastable emulsions one

advantage is the easier flotation of leakage oil, abrasion and dirt; stable emulsions are generally easier to control.

As a general rule, the emulsion is checked several times a day during operation and particular attention is paid to the degree of dispersion, the cleanness of the sheet and the risk of corrosion. The pH values are frequently between 6.0 and 7.0, the chloride content is not to exceed 20, the sulfate content 40 or the iron content 100 mg/L.

Re-rolling. In so-called skin pass rolling mills the strip must be re-rolled after annealing to improve the flatness and achieve the required material properties (forming changed tensile strength, tensile yield strength etc.). The reduction in thickness is only about 1 to 3 %. The strip is rolled dry or wet with special temper rolling oils, which, in particular, increase the strip cleanliness. Skin pass fluids have also proved to be successful for providing a uniform mat finish, because the surface of the temper rolling roll closes more slowly and does not pick up dirt or friction particles.

Skin pass fluids are synthetic aqueous solutions and mainly contain surfactants as well as organic and inorganic acid derivatives as corrosion protection components. Normally these are free of sodium nitrite and must be compatible with the subsequently applied corrosion protection oils and prelubes.

Finest Sheet Cold Rolling. Rolling is carried out with semistable high fat content emulsions by the so-called direct application of fat oil dispersions. In the case of direct application, natural fats such as palm oil or animal tallow are often prepared as a 10 to 20 % dispersion in completely softened water in large mixers. The drops of fat oil are approx. 50 µm in size. The fat and water are separated during the return run, treated and used again. Recovered fat can be used for rolling up to an acid number of approx. 20 mg KOH/g.

Where semistable emulsions are used initial concentrations of 3 to 6 % in fully softened water are employed. The size of the drops in such emulsions is between 10 and 50 µm.

Cold Rolling of High Alloy Steel Sheet. Higher alloyed steels, especially high grade stainless steels, are rolled on multiroll stands with a preference for lubricants which do not mix with water.

The rolling speeds, which depend upon the alloy and material thickness, can be up to 500 m/min, in which case, for example, high grade stainless steel hot strip be reduced by up to 85 % in eleven passes without intermediate annealing. Frequently, however, annealing, pickling and re-rolling have to take place in order to achieve the required strip quality.

The selection of the rolling oils has a decisive influence on the surface finish of the sheet. Mat surfaces are produced when the viscosity is too high even when using ground or polished work rolls. This is almost always undesirable in the case of high grade stainless steels. This is why in practice preference is given to mineral oils with viscosities of ca. 15 to 20 mm^2/s at 20 °C which have the closest possible boiling range [305].

13.3.2. Rolling Aluminum Sheet

Hot Rolling. Depending upon the alloy and required reduction in thickness the blocks are preheated to 450 to 580 °C before hot rolling. With a rolling speed between 180 and 300 m/min in the reversing process and appropriately higher speeds in tandem stands, the material is rolled with stable emulsions in an initial concentration between 2 to 6 % and an upstream temperature of 35 to 60 °C. The temperature in the last pass, depending upon the alloy, is still 280 to 230 °C.

The concentrates comprise mineral oil hydrocarbons or synthetic hydrocarbons with polar additives (ester, fatty acids, fatty alcohols), surfactants and further antiwear substances, where needed.

Fatty acids form aluminum soaps which can cause too high slip and tarnishing. This is why they are only to be used in low amounts.

Decisive for the lubrication and quality of the surface finish is the development of a uniform, fine coating of aluminum pick-up (roll coating) on the work rolls. If the coating is too thin, the friction conditions are unfavorable and frequently unstable. On the other hand a roll coating which is too thick causes uncontrolled release of parts of this coating which, in turn, leads to pick-up rolling and surface faults. To prevent this, excessive pick-up is removed from the work

rolls during the rolling process [306] by means of brush rolls. Exact control of the temperature of the work and back-up rolls is accomplished by means of specific emulsion dosing to obtain a favorable hot strip profile.

Cold Rolling. After soft annealing at temperatures from 370 to 430 °C, finish rolling is carried out on cold wide strip lines at speeds up to 2700 m/min. The sheet thickness is between 0.1 and 3.0 mm but the major amount of rolled strip is about 0.6 mm thick and achieved in two to seven passes.

Despite the advantages of better heat dissipation, lower fire risk and less expensive health protection, water-miscible rolling oils [307] have been unable to establish themselves for this application, because of, for example, patch forming as a result of residue moisture in the round coil, and hydrogen embrittlement of the work rolls can only be controlled to a deficient degree.

When making up strip rolling oils, the main attention has to be paid to the selection of the base oil. Particularly suitable are paraffinic hydrocarbons with a viscosity which is not too high, in order to avoid mat surface finishes. Consequently, closely cut base oils with flash points above 85 °C and a viscosity from 2 to 4 mm^2/s at 20 °C are mainly considered. The most popular additives are straight-chain alcohols, acids, and esters with chain lengths from 10 to 14 carbon atoms as well as oxidation inhibitors. The activation level seldom exceeds the 5 % mark.

In principle, foil rolling oils differ from strip rolling oils only by a lower additive content, occasionally also by lower viscosity and preferably by a very low aromatic content to ensure compliance with the stipulations for use in the food sector.

As is the case with hot rolling, to avoid spotting synthetic or barely-synthetic special lubricants and hydraulic oils are also used when cold rolling on the roll stand and in the rolling operations.

13.3.3. Rolling of Other Materials

Copper and its alloys are generally rolled in a hot roll process with water, i.e., without special lubricants, although occasionally with stable slightly fatty emulsions.

Generally stable emulsions with fatty oils and synthetic esters are also used for cold rolling. Under all circumstances, staining of the bright, mostly decorative surfaces by the emulsion or its contents has to be avoided. Consequently special attention must be paid to ensure the absence of substances containing sulfur [308].

Fatty oils are used for cold rolling of *titanium*.

Zinc is rolled in a semihot state at 200 °C, very often dry, or cold with a slight lubrication using low viscosity oils with polar substances or emulsions. By heating to between 120 to 150 °C when cold rolling, a large part of the lubricant is volatilized so that no further cleaning is necessary.

Tin and lead are generally cold rolled. Low viscous special lubricants are used for special alloys (solders and similar materials). Tungsten and molybdenum rolling has to be carried out at high temperatures under inert gas due to sensitivity to oxidization at high temperatures. Alternatively coating with glazes is also possible. Semi-hot or cold rolling is carried out with solid matter content or strongly polar oils with additives.

13.4. Lubricants for Solid Metal Forming

Under this heading, a large number of forming methods are included, most important are extrusion and forging.

Mainly processes are classified on material flow and the type of the tool used. However, there are frequently no clear differences between forging and extrusion.

Important processes include:

a) *Upsetting* is a process with compression between flat dies.
b) *Extrusion*. During extrusion processes, the workpiece is placed in a container and compressed by means of ram movement. Extruded products can be hollow or solid. According to the material flow, forward (direct), backward (reverse) and cross procedures are distinguished.
c) *Impression die forging* is the dominant hot forging method economically. This is also

reflected in the significance of this group of lubricants.

Closed die forging is a special form of impression die forging. Here the filling of the die is not supported by the development of a flash. There is no possibility for excessive material to escape, and vent holes are provided for vapor generated from the lubricant to escape.

d) *Open die forging* is different from impression die and closed die forging in that the metal is never completely enclosed as it is being shaped by the dies.

Cold Extrusion of Steel (Extrusion Oils).

Lubricating Oils. Of particular significance is the lubrication with EP oils, especially when working with wire without surface pretreatment of the blank metallic shearing surfaces. In the case of tools with extremely long service life, the forming is possible with the majority of highly active EP substances. An example of this is the production of inner square socket-head screws.

Apart from lubricating properties, the extrusion oils must have high thermal stability; the oil is overheated locally on the extrusion bodies and tools and temperatures over 90 °C can occur in the circulating system. The extrusion oil also has an essential cooling function, especially in the case of high speed automatic machines. No adhesive residue must remain as a result of the temperature stress as these could cause irregularities in operation.

The preferred viscosity range of extrusion oils is between 35 and 65 mm^2/s at 40 °C. Selection criteria for the initial viscosity are the workpiece temperatures, size of the extruded parts, machine pumping facilities and the specific criteria for the transfer between the working stages, as well as the thickening effects as a result of enrichment by abraded phosphate particles where phosphatized material is concerned.

EP additives containing sulfur and chlorine play a role in extrusion oils. Additives containing chlorine have lost their significance in Europe due to the environmental problem described earlier. Apart from the sulfurized fatty oils there are also other products in the polar additive sector such as thermally stable synthetic esters (also as base oils). Sulfurized mineral oils, sulfurized fatty oils and polysulfides play a special role as sulfur carriers. Zinc dialkyldithiophosphate smoothes the surface roughness of the workpieces [309]. Alkyl and arylphosphoric acid esters and even phosphoric acid partial esters are also used [310]. Because the thermal stress is considerable when using chlorinated products, particular attention must be paid to their stability and the risk of corrosion on machines and extruded parts. A degreasing of the parts directly after extrusion is recommended when using strongly chlorine containing oils.

For the most important areas of application, extrusion oils are classified by type and amount of additive into four classes [311]

- standard screws and high tension hexagonal bolts: oil with polar additives and EP additives on a phosphorus basis (also suitable for nonferrous metals)
- larger size bolts and hexagonal nuts produced from zinc phosphatized wire on multistage presses: oils with polar EP additives, copper active
- cylinder bolts with an inner hexagon recess or inner toothing made of wire on multistage presses (larger dimensions): oils with an active proportion of polar additives and EP additives on a sulfur basis, copper active
- high tensile rust and acid resistant steels subject to high deformation: maximum alloyed oils with a very high share of EP additives on a (chlorine) sulfur and phosphorus basis, copper active

Thermally stable, biodegradable ester oils with excellent tribological characteristics will gain more significance in the future.

Phosphate Coatings and Soap Lubricants. Phosphatization has remained the most important method of surface treatment for cold extrusion of steel until today and has undergone further technical development in conjunction with other lubricating systems. Particularly favorable is the ability of the layers of zinc phosphate to go along with large expanding surfaces without breaking away when extruding.

The high resistance to pressure, shearing and adhesion during extrusion of zinc phosphate coatings are considered as positive.

A fine crystalline coating approx. 5 to 7 mm is to be used for oil lubrication on multistage presses. Layers, which are too thick, lead to problems due to formation of layers of phosphate on the tools. This system is preferred for

parts with low piece weights such as screws, nuts, bolts or spark plug bodies produced on multistage presses.

Alkali soap in connection with a zinc phosphate coating has gained particular importance. In this case, not only the absorptive and chemically absorptive binding of the lubricants to the workpiece surface is neutralized but there is also considerable chemical conversion of the soaps with the zinc phosphate.In the aqueous solution the alkali soap reacts with the zinc phosphate coating according to the following formula:

$$Zn_3(PO_4)_2 + 6\,CH_3(CH_2)_nCOONa \rightarrow 3\,Zn[CH_3(CH_2)_nCOO]_2 + 2\,Na_3PO_4$$

zinc phosphate + sodium soap → zinc soap + sodium phosphate

Some 50 to 60 % of the phosphate coating can be converted depending on temperature, dwell time, concentration and the developing phosphate layer. The type of soap also plays a considerable role in this respect. Salts of stearic acid are more reactive than the salts of oleic and palmitic acid.

The zinc soap developed by the reaction leads to lower coefficients of friction when forming and the firm anchoring with the phosphate layer is particularly favorable for the lubricating operation.

The reactive soaps are supplied by the manufacturers in powder or flake form and mixed by the user with water to provide 2 to 10 % soap solutions, depending upon the degree of difficulty. The parts are soaped by immersion over a period of 2 to 6 min at bath temperatures from 60 to 85 °C [312–314].

Solid Lubricants. Although soap lubricants in conjunction with zinc phosphate coatings are preferred for medium to larger sized parts, structure-effective solid lubricants, especially molybdenum sulfide, are used for smaller parts.

As a general rule the solid lubricants are applied to a phosphate layer as dry powder lubricants by tumbling or from aqueous suspensions by immersion or spraying. Application by immersion follows in dipping baskets or rotating screen tubs [311], [315–318].

In a few cases, solid lubricants can be applied as suspensions in mineral oils, synthetic oils, or even solvents. In special cases, this method can solve wetting problems better than aqueous suspensions. In general, however, the aqueous dispersions offer considerable advantages as carrier fluids as a result of their environmental friendliness, especially when compared with organic solvents, and can also be better integrated in the wet treatment of workpieces.

Warm Extrusion and Forging. The yield stress decreases with the temperature increase in the workpiece material and as a result lower forming forces and higher degrees of workability can be achieved. This effect is utilized to some extent through the existing forming heat (up to 250 °C) even when cold extruding (without preheating the blanks), especially when working on high speed multistage presses.

Warm forming has the greatest significance for high alloyed steels and special materials. The method is applied when the parts cannot be cold formed or when it is possible to ensure more economical production by the warm process by less forming stages.

A phosphate layer is expedient at temperatures under 400 °C – as when cold extruding.

In the temperature range up to 350 °C zinc phosphate coatings serve as carrier layers; the most important fluids are mineral oil based oils with a high flash point, polyglycols and polybutenes; they can be applied as loss lubrication and at temperatures up to about 300 °C as circulating lubrication. Solid lubricants can also be suspended in the above-mentioned oils; in this case mainly MoS_2 and graphite. Aqueous MoS_2 and graphite suspensions are also suitable.

The lubricants mostly used in the temperature range 350 to 500 °C are graphite dispersions in water or organic carrier media. The decomposition of synthetic polymer oils is intentionally accepted, if necessary. In this case thermal resistance limits are set for MoS_2 lubricants.

In the temperature range 500 to 600 °C aqueous graphite dispersions are given preference and applied by spraying. Decomposition of the solid lubricants graphite and MoS_2 can be prevented when these are mixed with boric oxide powder [319].

At temperatures > 600 °C the lubricants and the application technology are similar to those applied for the hot forging process. In addition to graphite, zinc sulfide has also proved successful as a solid lubricant because of its particular re-

sistance to temperature in individual cases; it is also used in operations with graphite and water soluble organic carriers such as polyglycols.

Hot Forging. The hot workpiece material (in the case of steel approximately 1200 °C) flows into the cavities of the die during the forming operation. This is carried out to some extent at a high relative speed which depends, firstly, on the speed of the striking tool (hammer or forging press) and, secondly, on the die.

In hot forging of steel workpiece temperatures are between ca.1100 and 1200 °C and die temperatures preferably between 150 and 300 °C (maximum up to 500 °C). The temperature of the lubricant layer is between 725 and 775 °C at a die temperature of 250 °C and a workpiece temperature of 1200 °C.

Graphite preparations have gained outstanding significance as lubricants. Colloidal preparations in oil and in water as well as pasty graphite lubricants are used.

Graphite preparations are generally applied as water-based suspensions. The wetting problems given in the case of aqueous graphite suspensions, especially at high forging temperatures, can be solved by incorporating an organic phase with appropriate surface active substances, either as an emulsion phase or even as a real solution.

The propellant effect can be improved through inorganic salts (alkali carbonate and bicarbonate) or through organic substances in aqueous solution or by dispersion. Bonding agents frequently on silicate or borate basis are used to form surface films.

If the die temperature is clearly under 200 °C or even under 150 °C when the lubricant is applied it may well be that no film can be formed by the aqueous dispersion, depending on the available evaporation time. In such cases organic carriers can be used which either evaporate more quickly or form an oily film. When selecting synthetic polymer oils, care must be taken that no toxic monomers develop during the depolymerization process during contact with the hot forging. In individual cases pasty graphite preparations are still being used.

Aluminum Forging. Because of their low weight and excellent mechanical properties, parts produced by massive forming from aluminum and aluminum alloys are gaining increasing importance. Because of the major adhesion problem, the technology in the usual mechanical presses with high deformation rates has still not been completely developed. The most extensively used lubricants are water-based graphite dispersions [320–323].

14. Lubricating Greases

14.1. Introduction

Definition. Lubricating greases can be defined as solid to semifluid products that represent dispersion of a thickening agent in a liquid lubricant. They usually contain additional compounds to impart special properties, and usually the thickening agent is a metallic soap. It is not easy to classify greases as either liquids or solids – the transitions are fluid.

Greases in general contain from 65 to 95 wt % base oils, from 5 to 35 wt % thickeners and from 0 to 10 wt % additives.

History. It can be speculated that grease-like lubricants were already known to the Sumerians and used by them in their wheeled vehicles from ca 3500 to 2500 B.C. [324]; it has also been stated that as early as 1400 B.C. the Egyptians used greases made from olive oil or tallow and lime to lubricate the axles of their chariots [325], although only pig fat was reported for that purpose by ancient authors such as Dioscurides and Plinius Secundus [326]. Probably the first grease of the industrial age was patented by Partridge [327] in 1835; it was a calcium grease, also made from olive oil or tallow. Greases based on mineral oils and thickened by soaps were probably first proposed ca 1845 by Raecz [328], and a sodium grease made with tallow was patented by Little [329] in 1849.

Much general information on greases is given in two encyclopedic monographs, published in 1937 and 1954 [330], [331].

Classification. Greases are named after the industry in which they are used, e.g., steel mill greases, after the kind of application, e.g., wheel bearing greases, after their prevalent application temperature, e.g., low-temperature greases, or

after their range of application, e.g., multipurpose greases. The meaning of the latter name has changed with the years [332] and the other names do not say very much about the quality of the performance of the greases in question.

Even today, greases are named according to the consistency classes defined by the US National Lubricating Grease Institute (NLGI) in 1938 and in accordance with the cone-penetration method developed in 1925 [333] (Table 42).

Table 42. Classification of greases by NLGI numbers.

NLGI number	Appearance	ASTM worked penetration (1/10 mm)	Application
000		445–475	gear greases
00	Semifluid	400–430	
0		355–385	
1	Soft	310–340	
2	Creamy	265–295	greases for bearings
3		220–250	
4		175–205	
5		130–160	
6	Soap-like	85–115	block greases

Nowadays the performance of lubricating greases is described by standards such as ISO 6743-9 [334] or DIN 51825 [335] defining mainly consistency, upper and lower operating temperature, water resistance, and load-carrying capacity, and for automotive greases by ASTM D 4950 [336], which has been followed by the consideration of reference greases [337] and the introduction of the NLGI Certification Mark [338].

But to some extent greases are best judged simply by the chemical and physical properties of their base oils and the agents thickening them – naturally the consistency of greases increases with increasing thickener content, and with it some of their properties change. These properties at the same time best reflect the reasonable limits of practical applications.

14.2. Components of Greases

14.2.1. Thickeners

Thickeners not only transform liquid lubricants into consistent lubricants, they change the properties of the liquid lubricants also (see Section 14.8). Commercially important thickeners are listed in Table 43 [339].

14.2.1.1. Simple Soaps → Metallic Soaps

A maximum thickening effect is achieved with carboxylic acids having 18 carbon atoms. Thus, soaps are usually prepared both from vegetable-derived 12-hydroxystearic acid [340], [341] and from animal- or vegetable-derived stearic acid [342], or from their esters, usually their glycerides, and from the hydroxides of elements of the alkali and alkaline-earth metals. Soaps, by gelling their base oils give greases most of their unique properties. They are not only present as crystallites and dissolved molecules, but above all in a separate phase represented by agglomerates called fibrils or fibers (see Section 14.4).

Soap Anions. The carbon chain length of a carboxylic acid affects the solubility and surface properties of a soap. Longer and shorter carbon chains than 18 carbon atoms reduce its thickening capacity. Increasing the chain length increases the solubility in the base oil, shortening the chain length reduces it. A branched alkyl chain lowers the melting point of a soap and reduces its thickening effect. Unsaturated carboxylic acids are more soluble in mineral oils and also reduce the thickening effect and lower the dropping point. Their use is limited because of their lower oxidation stability. Hydroxyl groups increase the melting point and the thickening effect of a soap because of its increased polarity.

Soap Cations. The soap cations also are responsible for essential properties of soap greases. The cations govern the thickener yield, the dropping point, the water resistance, and, to some extent, the load-carrying capacity of a grease (see Section 14.8).

In 1996 greases based on simple soaps still accounted for more than 70 % of known world production [343]. Lithium soaps were the most important, with ca 50 %, then the calcium, sodium and aluminum soaps. The importance of the latter has steadily decreased during recent decades.

Table 43. Competitiveness of thickeners

	I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII	Sum
Lithium 12-hydroxystearate	2.5	1.0	2.0	1.5	2.0	2.0	2.5	1.5	2.5	2.0	1.0	3.0	2.0

Lithium complexes	1.5	2.0	1.5	2.0	1.5	2.0	2.0	2.5	1.5	2.0	2.0	2.5	1.9
Calcium complexes	2.0	3.0	2.0	2.0	1.0	1.5	1.5	3.0	1.5	2.0	2.0	2.0	2.0
Aluminum complexes	2.0	2.0	2.0	2.5	1.5	2.0	2.0	2.5	2.0	2.0	2.0	2.5	2.1
Inorganic thickeners	1.5	1.0	1.0	3.0	3.0	1.0	3.0	1.0	3.0	3.0	2.5	3.0	2.2
Polyureas	1.0	1.5	1.5	2.5	2.0	1.5	2.5	2.0	3.0	3.0	1.0	2.0	2.0
Terephthalamates	1.5	1.5	1.5	1.0	2.5	1.5	2.0	1.0	2.5	2.0	1.0	2.0	1.7
Calcium – sulfonate complexes	2.0	3.0	2.0	2.0	1.0	2.0	1.5	3.0	1.0	1.0	2.0	1.5	1.8
Carbamate-like thickeners	2.0	1.5	2.0	2.0	2.0	2.0	2.5	1.5	2.0	2.0	1.0	2.0	1.9

I = high temperature, II = low temperature, III = aging, IV = compatibility, V = oil loss, VI = toxicity, VII = tackiness, VIII = flowability, IX = load, X = shear, XI = friction, XII = wear.
1.0 = excellent, 2.0 = average, 3.0 = poor

Lithium Soaps. Lithium soap-based greases are usually prepared by reacting lithium hydroxide as a powder or dissolved in water with 12-hydroxystearic acid or its glyceride in mineral oils or synthetic oils. The production temperature is between 160 and 250 °C, depending on the base oil and the type of reactor in use. The dropping point of a mineral oil-based NLGI 2 grease is usually between 185 and 195 °C. For such a multipurpose grease ca 6 wt % of soap is required with a naphthenic oil, ca 9 wt % with a paraffinic oil, and ca 12 wt % with a polyalphaolefin, and a kinematic viscosity of ca 100 mm^2/s at 40 °C. The thickening effect depends not only on the carbon distribution ($C_{aromatic} + C_{naphthenic} + C_{paraffinic}$) in a base oil, but also on its viscosity.

The fiber size in lithium 12-hydroxystearate greases is usually between 0.2×2 and $0.2 \times 20\,\mu m$. Good multipurpose properties, e.g., a high dropping point, good water resistance, good shear stability – which has been related to hydrogen-bonding of the hydroxyl groups – and good response to additives are the reasons why lithium 12-hydroxystearate-based greases have now been the most popular for more than half a century. They have found a wide range of applications from EP greases based on oils with kinematic viscosities of ca 200 to 1000 mm^2/s at 40 °C for heavy loads, through multipurpose greases based on mineral oils with kinematic viscosities from 60 to 120 mm^2/s at 40 °C for all kinds of bearings, greases made with diesters or polyalphaolefin oils and kinematic viscosities of 15 to 30 mm^2/s for high-speeds, to those with oil-insoluble polyalkylene glycols for gears. The lower and upper application temperature limit for a lithium soap thickened grease, as for all other greases, depends mainly on the physical properties of its base oil (see Section 14.3). Oil separation has been discussed as a criterion for both lower and upper application temperature limits [344]. In recent years attempts have been made to improve the structural stability of lithium soap-based greases by use of reactive polymers [345], [346].

Calcium Soaps. Greases based on calcium 12-hydroxystearates (anhydrous calcium soaps) are produced in the same way as lithium soap-based greases, but at temperatures between 120 and 160 °C. The size of their fibers lies between those for lithium soaps and hydrated calcium soaps. The greases can be used up to 120 °C. Their dropping point is between 130 and 150 °C, depending on their base oil. They usually have a very good corrosion resistance and good oxidation stability; when prepared from suitable base oils they are possibly the best low-temperature greases.

Calcium soaps mainly based on stearic, palmitic, or oleic acid still are called hydrated calcium soaps. For these greases the cost of raw materials, and the performance levels, are lowest. Calcium soap greases are prepared by neutralization of a slurry of calcium hydroxide in water with fatty acids or fats in mineral oil. Sta-

ble greases can only be obtained in the presence of some water, usually ca 10 wt % of the soap. The water content is usually adjusted in a second step in a stirring, or cooling vessel. The fiber size is usually ca $0.1 \times 1\,\mu m$. When the water is removed, the grease structure collapses. The dropping point of this type of grease is therefore only 90 to 110 °C and the upper application temperature limit is only ca 80 °C.

The greases have very good water resistance and good adhesive properties. Because their manufacture is rather demanding in relation to the performance obtained, their importance is declining rapidly.

Sodium Soaps. Compared with lithium and calcium 12-hydroxystearate greases the importance of greases based on sodium soaps is nowadays low, although in the form of semifluid products they still are of some interest for the lubrication of gears. Sodium greases made from fatty acids or fats have dropping points of ca 165 to 175 °C. Their upper temperature limit is ca 120 °C. Products are available with short and long fiber structures; the latter reaching up to $1 \times 100\,\mu m$ and are responsible to some extent for the rather high load carrying capability in gears. Although the greases have extraordinary good corrosion-preventive properties if only small amounts of water are present, their main disadvantage is the solubility of the sodium soaps in larger amounts of water; this leads first to gel formation, which dramatically increases the apparent viscosity, and later to breakdown of the whole structure.

Aluminum soap-based greases are usually produced with pre-manufactured aluminum soaps, usually aluminum stearate. They have dropping points of up to 120 °C, their upper temperature limit is 80 to 90 °C – above 90 °C they tend to gel. Typical of this soap is a particle size of $< 0.1 \times 0.1\,\mu m$, which is to some extent responsible for the low shear stability and the pronounced thixotropic behavior of the products. Aluminum greases are usually very transparent and smooth. They have good water resistance and adhesive properties, but have been widely replaced by lithium greases, partly because, for consistent products, aluminum greases must not be stirred during the finishing process but poured into pans and left for several hours to cool.

Cation Mixed Soaps M_1X/M_2X. Mixtures of soap greases with different cations, mainly lithium – calcium, calcium – sodium, and sodium – aluminum are called mixed-soap greases. Their properties largely depend on the relative proportions of the components. Lithium – calcium greases have better water resistance than pure lithium greases and often better shear stability. As long as the proportion of calcium soap does not exceed 20 wt % their dropping points, 170 to 180 °C, are close to that of the lithium soap alone, and their wear and friction performance are better than that of pure lithium grades [347]. Some calcium – lithium greases perform better than pure calcium 12-hydroxystearate greases.

Lithium – calcium greases have become quite popular as specialized multipurpose greases. Greases mainly based on sodium-aluminum stearate, have been used as substitutes for lithium greases. Cation mixed soap greases are usually manufactured by a one-step process, because the stability of mixtures of finished products are not always satisfactory.

Anion Mixed Soaps MX_1/MX_2. Because of the animal and vegetable origin of the acidic components most simple soap-based greases are already anion mixed soap based. Nevertheless the fine-tuning of multipurpose greases and specialized multipurpose greases is, especially for the comparatively pure 12-hydroxystearic acid, often achieved by substituting small amounts of the main acid by a complementary acid, e.g., behenic, naphthenic, or stearic acid.

14.2.1.2. Complex Soaps

Simple soaps can form complex soaps with salts of other acids. Examples are inorganic acids, e.g., boric and phosphoric acid, or with short-chain carboxylic acids, e.g., acetic acid, or with dicarboxylic acids, e.g., azelaic [348] and sebacic acids [349]. The addition of complementary salts always leads to an increase in the dropping point from ca 50 to 100 °C and to reduced oil separation, primarily because of the increased thickener concentration, and, thus, for the same reason, to reduced suitability for low-temperature application. Because of their superior properties complex soap-based greases have

become very popular and nowadays account for ca 20 % of all greases sold.

Lithium Complex Soaps. Apart from their higher upper-temperature limit, between 160 to 180 °C, some lithium complex soap-based greases perform similarly to the corresponding simple soap-based products. Of the many known formulations the most widespread is based on 12-hydroxystearic acid and azelaic acid, introduced in 1974 [350]. The first complex was based on 12-hydroxystearic acid and acetic acid and was patented as early as 1947 [351]. The lithium complex soaps with the best load-carrying capacities contain boric or phosphoric acid. The fiber size of such a complex soap does not differ much from that of the simple soap and it does not change significantly with common shear. In addition to azelaic and boric acids, other acids have also been examined systematically

Lithium 12-hydroxystearate
+
Lithium adipate
Lithium azelate
Lithium dimerate
Lithium sebacate
Lithium terephthalamate
...
Lithium borate
Lithium phosphate

With a share of about 10 %, lithium complex greases are the most widespread complex greases.

Calcium Complex Soaps. All commercial calcium complex greases contain acetic acid as a complementary acid. The complex was first described in 1940 [353]. Calcium complex greases have good shear stability and water resistance, a low oil separation, and good load-carrying capacity. Their upper temperature limit is 160 °C. Because of the formation of ketones, from about 120 °C pronounced hardening can occur. It has, nevertheless, been possible to retard hardening with the aid of polymeric structure-modifiers [354].

Calcium Sulfonate Complex Soaps. Competitive greases based on this complex were first offered in 1985 [355]. Initially they comprised in situ-produced overbased calcium sulfonates and the calcium salts of other sulfonates, of 12-hydroxystearic acid, and of boric acid [356]. The complex could be improved by replacing calcium borate by phosphate [357]. Greases containing calcium acetate instead are also possible [358]. The greases are extraordinarily corrosion protective and resistant to shear and have load-carrying capacities that can be matched only by greases of other soaps with very many additives. Their dropping points start at ca 220 °C, but their upper temperature limit is ca 160 °C. Some grades can, nevertheless, survive temperatures up to 250 °C for several hours. It can be expected that these greases will become even more important in the future, although, because of their high thickener content their low-temperature pumpability is limited.

Aluminum Complex Soaps. Today only one of the possible aluminum complexes is still widely used. It comprises aluminum stearate and benzoate, and was first patented in 1952 [359]. Aluminum complex greases of that kind have good water resistance and good low-temperature properties. Their importance has decreased in recent years, although attempts have been made to make them more attractive again. This might be possible for food grade and biodegradable greases (see Section 14.10).

Other Complex Soaps *Sodium complex soap-based greases* have been used because of their suitability for high relative velocities, but like the simple soaps they lost importance because of their limited water resistance; *barium complex soaps* have been replaced almost as completely as the simple soaps.

Titanium complex greases were patented in 1993 [360]. They are based on 12-hydroxystearic and terephthalic acid. Of their properties [361] good load-carrying capability is most worthy of mention.

14.2.2. Other Ionic Organic Thickeners

Of many possible soap-like salts only the sodium and the calcium salts of stearylamidoterephthalic acid are used on an industrial scale.

(14.1)

They were patented in 1954 [362] and proposed for multipurpose greases in 1957 [363]. Greases of this kind have dropping points of up to 300 °C and upper temperature limits of up to 180 °C. Although they have the thickening effect of simple soap greases they behave like complex greases; this makes them valuable wide-range greases. The thickeners are among the most expensive and are preferably used with synthetic base oils. Complex soaps comprising terephthalamate and benzoate have been described and complexes of aluminum stearate with terephthalamates have also been investigated [364].

14.2.3. Nonionic Organic Thickeners

Of a rather large number of theoretically suitable compounds, only the oligoureas, commonly called polyureas, have gained real industrial importance.

Diureas and Tetraureas. Oligourea thickeners were introduced in 1954 [365]. The reaction products of one molecule of di-4,4′-isocyanatophenylmethane (MDI) or other diisocyanates with two molecules of monoamines are called diureas.

(14.2)

Tetraureas are the reaction products of two molecules diisocyanate with one molecule of diamine and two molecules of monoamine.

(14.3)

Depending on the performance required aliphatic or aromatic amines or mixtures of both are used. With excess diisocyanate three-dimensional structures are built along biuret-like bridges.

(14.4)

The upper temperature limit of oligourea greases is not determined so much by the stability of the thickener, the decomposition of which usually starts slightly below 250 °C, as by the stability of the base oil. These greases are, therefore superior to soap-based greases when the application temperatures exceed 180 °C. When an oligourea grease based on polyalkylene glycols is overheated, ideally, only gaseous products are formed. Although tetraureas also have some advantages [366], the trend in polyureas will probably be toward diureas [367]. Oligourea complex greases containing calcium acetate were introduced in 1974 [368]; others containing carbonate [369], [370] and other complementary salts followed and are still favored for some applications. Although soap-based greases cannot compete with oligourea greases at higher temperatures, below 180 °C lithium complexes, for example, have at least equal performance [371].

Carbamate-like thickeners are related to the oligoureas and simple soaps, and have properties intermediate between those of these groups.

(14.5)

Other Nonionic Organic Thickeners. Polymerized perfluorinated hydrocarbons, usually micronized poly(tetrafluoroethylene)

(PTFE) powders, are the choice for greases that must function at temperatures above 220 °C, with an upper temperature limit of about 270 °C. For applications of this kind their liquid oligomers or preferably corresponding perfluoroalkylene ethers must be chosen as base oils [372–374]. Polymers such as polyamides or polyethylenes are mainly used as additives.

14.2.4. Inorganic Thickeners

To be suitable for use in lubricating oils inorganic thickeners must be treated with between 5 and 10 wt % reactive organic compounds. Without this treatment they would act like fillers, co-thickeners, and solid lubricants, that only at concentrations above ca 40 wt % yield grease-like pastes. Apart from these hydrophobic agents additional polar activators, e.g., acetone, ethanol, or, for safety reasons, propylene carbonate [375], are needed to accomplish gelation. They are used at a level of 10 wt % relative to the thickener. The thickeners themselves are stable up to temperatures of > 300 °C, but the resulting greases or gels are mainly used for applications up to 200 °C that do not require too pronounced shear stability. This is partially because of the diameter of the primary parts, only ca 0.05 µm. The tendency of inorganic thickened greases to hardening and oil separation during storage, and their sensitivity to polar additives can to some extent be overcome by addition of functionalized polymeric agents [376].

Clays. Bentonite-type aluminosilicates, mainly the smectites montmorillonite and hectorite [377], are the most important inorganic thickeners. They are usually treated with quaternary ammonium compounds, e.g., trimethyl stearyl ammonium chloride, and the activators mentioned above.

Highly dispersed silica is usually prepared by flame hydrolysis of silicon tetrachloride (→ Silica, Chap. 6.1.1.); it is made more suitable as a thickener by treating it with, e.g., silanes, silazanes, or siloxanes [378]. One advantage of these products is the low temperature-dependence of their consistency [379]. With suitable base oils and activators they form white to transparent gels that are used in food or medical applications.

14.2.5. Miscellaneous Thickeners

In principle inorganic and organic pigments of all kinds can be used as thickeners or co-thickeners or at least as fillers. The transition to lubricant additives is fluid. Only the inorganic materials soot and expanded graphite [380] and the organic phthalocyanines [381] are sometimes used on an industrial scale.

14.2.6. Temporarily Thickened Fluids

Under defined conditions liquids and suspensions of solids in liquids have significantly increased viscosities.

Some *liquid crystalline systems* are suitable as lubricants under the influence of changes in pressure [382], or temperature [383]. Some of the solutions that can form liquid crystals in limited concentration ranges [384] are comparable with consistent lubricants and some liquid crystals in concentrated point contacts are even superior [385].

Electrorheological or *electroviscous fluids*, i.e., suspensions of micronized highly polarizable and hydrophilic porous solids, are characterized by an enormous increase in apparent viscosity, when subject to electric fields. Originally silica in silicone oil was used with water as a promoter, later polyurethanes without a promoter in hydrocarbons. The first practical applications go back to 1942 [386]. electrorheological fluids are increasingly used in hydraulic valves, shock absorbers, and clutches [387], [388].

Magnetorheological fluids [389], suspensions of micronized transition elements, mainly ferrites, behave similarly in magnetic fields. Both electrorheological and magnetorheological fluids have also been named 'smart fluids'. They contain between 20 and 60 % solid particles which form more or less branched chains in the applied fields; they therefore act as Bingham plastics (see Section 14.7).

14.3. Base Oils

In principle all the lubricating oils already described in Chapters 4 and 5 can be used as base

oils for greases, but in general only oils with kinematic viscosities from 15 to 1500 mm^2/s at 40 °C are used. The oils with the lowest viscosities and the best low-temperature properties have the lowest operational temperatures at the highest speeds. The oils with the highest viscosities have the best performance at the lowest speeds and the highest loads, the lowest evaporation loss, the strongest adhesion and the best water or solvent resistance.

14.3.1. Mineral Oils (see Chap. 4)

Oils with low *VI*s usually require less thickener than those with high *VI*s and the same kinematic viscosity. The latter can be used over a wider temperature range and are, therefore, preferred nowadays. In principle the thickening effect (yield) depends on the difference between the solubility parameters of the base oil and thickener [390–393]. Because oil separation depends on the concentration of thickener, at a given temperature oil separation is most pronounced for greases based on low *VI* oils, e.g., aromatic oils or alkylbenzenes. Oil separation goes through a minimum with increasing kinematic viscosity for a given kind of base oil. This can easily be understood when only the dependence of particle interactions on the size of the involved particles is considered. Some of the specific properties of greases also depend on the ratio of the temperature and pressure coefficients of the viscosity of their base oils. If all this is taken into account, the effect of even a small change in base oil composition on the performance of a grease should not be underestimated [394].

14.3.2. Synthetic Base Oils (see Chap. 5)

Because of their cost, synthetic oils are used in greases only when the performance required cannot be achieved with mineral oils [395]. Even today greases of this kind represent less than 5 % of overall grease consumption.

Synthetic Hydrocarbons. Polyalphaolefins [396] are the ideal base oils for wide temperature-range greases. They are usually used in the same viscosity range as their mineral oil equivalents, but whereas the upper kinematic viscosity border of the former is ca 50 mm^2/s at 100 °C, polyalphaolefins and similar products are available to ca 2000 mm^2/s at 100 °C. In contrast with mineral oils they are preferably shrinking rather then swelling polymeric sealing materials. Usually, therefore, esters with softener properties must be added. Greases made from polyalphaolefins with standard viscosities are usually meant for lifetime lubrication, those made from mixtures with mineral oils (semisynthetic oils) and are used in specialized greases to increase lifetime.

Polybutenes and comparable polymers are usually applied to increase the viscosity of standard base oils; occasionally they are used as a base oil component, or even the only base oil.

Other Synthetic Base Oils. High molecular-mass esters made from diols or polyols and dicarboxylic acids with viscosities $> 2000\ mm^2/s$ at 40 °C are used as base oils in greases that must be solvent resistant.

In contrast with other greases silicone greases [397] are better distinguished according to the properties of their base oils [398]. The kinematic viscosities of silicone oils for greases range from ca 75 to ca 10 000 mm^2/s at 40 °C. Dimethylsilicone oils are physiologically inert; when thickened with highly dispersed silica they are mainly used as sealants or in applications where specific electrical and thermal conductivity is important.

Partially phenylated dimethylsilicone oils have very good low-temperature properties and are used with all types of thickener, depending on their (often military) application. Partially fluorinated dimethylsilicone oils are usually thickened with PTFE powders.

Apart from being suitable for temperatures up to 270 °C perfluorinated ethers thickened with PTFE powders are the only greases that can work in the presence of aggressive chemicals such as oxygen or chlorine. This is also their main advantage over the corresponding greases based on partially fluorinated silicone oils.

14.4. Grease Structure [399–402]

Greases have a more or less distinct lattice structure, soaps therefore form a framework of

string-like aggregates comprising micelles and crystallites that are called fibrils or fibers, the base oil is embedded in this framework. The oil is probably bound in three ways: firstly by molecular attraction between polar thickener and oil areas; secondly by capillary forces; and thirdly by mechanical occlusion. In soap-based greases small changes in the concentrations of the free acids and bases have a large effect on the shape and size of the aggregates. Even today it has not been definitively decided whether soap-based greases fit into the system of colloids (→ Colloids) or are of a more crystalline nature. Macroscopically the thickener particles are agglomerates of crystallites and micelles and dissolved components the size of which is limited by the method of homogenization. The nature of grease-like products formed with inorganic thickeners, pigments, or ferrites, is, however, not as difficult to describe. Here the laws of colloidal chemistry and physics can usually be applied fully [403].

The structures of liquid crystals are rather different (→ Liquid Crystals) [404]. Study of these has revealed much of interest in recent years [405].

14.5. Additives

Most of the additives already described in Chapter 6, can be used in greases also, and in the same way, although in general at clearly higher concentrations (Table 44). Interactions of thickeners and additives must therefore always be considered.

Table 44. Usual grease additive levels (%)

Antioxidants	0.10 – 1.00
Corrosion inhibitors	0.50 – 3.00
EP/AW additives	0.50 – 5.00
Metal deactivators	0.05 – 0.10
Solid lubricants (black)	1.50 – 3.00
Tackifiers	0.10 – 1.00

Structure Modifiers. Greases always contain compounds that affect the structure of the thickener itself to the same extent as they act as additives for the greases as a whole. These compounds are mainly water, glycerol, excess fatty acid, and excess alkali metal/alkaline-earth hydroxides. Interactions between structure modifiers and additives, e.g., that between EP additives and glycerol [406] or stearic acid [407], can severely affect the performance of a grease. Another structure modifier of greases that can easily be overlooked is the necessarily incorporated air. Though the air content must be limited, of course – often $< 3\,\%$ [408] – without air the transport of a grease through a long pipe would be almost impossible.

Antirust Additives (Corrosion Inhibitors). The most efficient corrosion inhibitor for a soap based grease is, when practicable, excess of the metal hydroxide. Sodium or calcium sulfonates, among the most powerful antirust additives, are also strong structure modifiers and can cause problems with most greases, especially greases made with inorganic thickeners. Imidazoline and sarcosine derivatives and alkenyl succinic acid esters are suitable inhibitors for soap-based greases; disodium sebacate is mainly used in gel greases. Carbodiimides have been recommended for use in ester-based greases, primarily to prevent hydrolysis [409].

Extreme Pressure and Antiwear Additives. Compounds containing heavy metals such as antimony or lead are, for reasons of toxicity, no longer acceptable as heavy-duty and antiwear additives, and even the use of zinc is disputed today, because of water pollution problems. Ashless additives, e.g., dithiocarbamates, dithiophosphates, and thiadiazole derivatives are slowly taking over [410] – the last also have corrosion-inhibiting properties [411] – and the importance of ashless alkylaminophosphorodithioates [412] as grease additives is also expected to increase.

Bismuth is one exception among the heavy metals. Additives containing this element have some of the properties of its toxic neighbors, but without their disadvantages [413], [414].

Solid Lubricants (see Chap. 15)**.** Because of their nature greases can contain these, or other additives that are insoluble in the base oil or base oil mixture, in rather high concentrations. For most applications an average particle size of the micronized solids of between 5 and 15 µm is acceptable.

Graphite and molybdenum disulfide are the oldest, the most common, and the by far best investigated solid lubricants for greases. Many manufacturers use them as mixtures, because they are believed to perform better. Fullerenes [415] have been tested successfully as solid lubricants [416], [417] but are still extremely expensive. The performance of molybdenum disulfide has been improved by the addition of zinc dithiophosphates [418] and by admixture of polyamide powders, urea resins, or salts of cyanuric acid derivatives. Admixture with PTFE powders does not give comparable results [419]. Molybdenum dithiophosphates and dithiocarbamates, rather than the disulfide, are of growing interest for joint greases [420].

Polytetrafluoroethylene, although rather expensive, is still the most common polymeric solid lubricant in greases. But high and ultrahigh molecular-mass polyolefin powders are becoming increasingly competitive.

Inorganic white solid lubricants, e.g., the hydroxides and diphosphates of some of the alkaline earth metals, improve the EP/AW properties of common greases and are especially suitable when the greases are subject to oscillations [421].

Friction Modifiers. In liquid lubricants carboxylic acids and their salts act as friction modifiers [422] and as additives for the boundary lubrication regime [423]. In greases that contain large amounts of these compounds, solid lubricants are sometimes called friction modifiers, instead [424], but sometimes polymeric additives also [425].

Some properties of greases, for example mechanical stability, can, to some extent, be improved only by use of polymeric additives; some properties, e.g., resistance against aggressive reagents cannot be improved by use of additives.

14.6. Manufacture of Greases

The properties of greases, especially metallic soap-based greases, depend not only on their composition but also, and to nearly the same extent, on the way in which the thickeners are prepared and dispersed.

14.6.1. Metal Soap-Based Greases

Batch Production with Preformed Metal Soaps. Greases can be prepared by dissolution or dispersion of preformed metallic spoaps in a suitable base oil with subsequent heating and cooling. But because of the higher costs of the thickener this method can be recommended only for highly sophisticated synthetic greases with precise chemistry or for functional base fluids that would react with the water or, even worse, with the steam generated during the neutralization process.

Batch Production with Metal Soaps Prepared In-situ. In general fatty acids or their glycerides or even their methyl esters are reacted with aqueous solutions or suspensions of the described metal hydroxides in part of the base oil. Each batch of a grease is produced by following a ten-point schedule.

1) dissolution or dispersion of the fatty acids in one third to two thirds of the base oil at temperatures up to 90 °C;
2) addition of the metal hydroxides as a solution or suspension in water;
3) heating to temperatures between 115 to 150 – or under pressure at 180 to 250 °C – depending on the type of reactor;
4) dehydration of the soap by heating to 180 to 200 °C or by pressure release;
5) crystallization during cooling to 150 to 130 °C combined with addition of more base oil;
6) addition of additives at temperatures below 80 °C;
7) (pre)filtration and homogenization with one of several possible devices;
8) adjustment of the specified consistency or flow pressure;
9) (end)filtration and deaeration; and
10) packing into containers

Different kinds of reactor or reactor combinations are used (Fig. 57). Single reactors are usually open vessels heated by gas, steam, or heating oil. Mixing is achieved with single action, double action, or counterrotating stirrers, usually designed as planetary stirrers, although turbines or dispenser disks can also be used.

Scrapers are always necessary, because of the need to move crystallizing material away from the walls to prevent a drop in heat transfer and degradation of the forming product. Sometimes the vessels can be used for evaporation or used under pressure. Since 1890, all in all the design has not changed and systematic optimization has not been reported [426]. During the reaction stage open reactors must not be heated much above 120 °C, because of the possibility of excessive foaming. Sometimes defoamers, for example low-viscosity dimethylsilicone oils, are added in small quantities during this stage.

Double or multiple reactors, the first being only a melting vessel, a Stratco contactor, or an autoclave – the last type of reactor can also be heated inductively – have some advantages in comparison with single and open reactors. The neutralization reaction is controlled more easily and the reaction time is shorter when the dehydration process is optimized [427]. The second vessel is either a finishing or a diluting vessel if several different grades are to be produced from one base grease. In each instance the main intention is to put the maximum thermal and mechanical energy into the reacting material in the minimum time. One further advantage of the multiple reactor process is that the first reactor never gets contaminated with additives. A third reactor is usually used for black, colored, or white greases.

When base oils such as silicone oils used for the in-situ production of soap greases, the thickeners are sometimes formed and dispersed in the presence of solvents which are subsequently removed by extraction or evaporation [428].

Continuous Production. Technology for the continuous manufacture of greases was first described in 1969 [429]. In principle a production unit consists of three elements only:

1) A tubular reactor – in which measured quantities of the base grease components are intensely mixed at pressures up to 2 MPa and temperatures up to 210 °C
2) A vacuum chamber in which dehydration of the product takes place
3) A finishing segment – usually a static mixer – in which oil and additives are added and homogenization takes place

The advantages of such a unit are its compact size (a few hundred liters only), its minimal energy consumption, and the uniformity of the product; the disadvantages are the difficulty of producing different ranges of products and the capacity of such units – far bigger than the need for common greases nowadays.

The finishing equipment comprises suitable pumps, filtration units, homogenization units (mills are still common although high-pressure injection homogenizers are preferable), deaeration units (vacuum pumps), and filling devices with geometries suitable for the types of containers to be filled – in a typical grease plant their range is usually from 400-g cartridges to containers holding 1 t.

14.6.2. Oligourea Greases

Oligoureas are usually prepared in a two-step process. In the first step the diisocyanate and the amine are separately dissolved or dispersed in appropriate amounts of the base oil. In the second step one of the two solutions or dispersions – usually that containing the diisocyanate – is added to the other portion [430]. The reaction is rather exothermic and, because of the toxicity of diisocyanates, the vessels must be sealed against the atmosphere during this step and subsequent heating. Because of the sudden and enormous increase in consistency very powerful stirring devices are necessary. To complete the reaction and for optimization of the thickener structure the greases are heated to 180 °C. Oligourea greases made in this way are preferably homogenized with kneaders or high-pressure injection homogenizers.

14.6.3. Gel Greases

For production of gel greases the raw materials are warmed to 60 to 80 °C only, to accelerate the activation and improve the gelation process. This is usually conducted in the same type of single reactor used for the one-step production of metallic soap-based greases. The consistency required of the product can best, and in many cases only, be achieved with the aid of high-pressure injection homogenizers or rotor – stator colloid mills [431], or, for polyester-based greases, with annular gear colloid mills [432].

Figure 57. Reactors for the manufacture of greases

Table 45. Twenty-four properties of greases.

Twelve phenomena	Twenty-four properties
High temperature	Maximum thermal stability
	Minimum evaporation loss
	Maximum viscosity
Low temperature	No (regular) crystallization
	Minimum viscosity
Aging	Maximum oxidation resistance
	Resistance to changes in structure
Compatibility	No reaction with nonferrous metals
	Maximum corrosion inhibition
	Maximum polymer compatibility
	Immiscibility with foreign liquids
	Deflection of foreign solid matter
Oil loss	Optimum oil loss[a]
Toxicity	No toxicity
	Biodegradability
Tackiness	Optimum tackiness[a]
Flowability	Optimum relaxation[a]
	Maximum pumpability
Load	Optimum elasticity[a]
	Maximum lubricating film thickness
	Maximum emergency running properties
Shear	Maximum mechanical stability, or
	Optimum relaxation time[a]
Friction	Minimum, or optimum friction[a]
Wear	Minimum wear.

[a] According to application.

ASTM D 0128-95	Analysis
ASTM D 1092-93	Apparent viscosity
ASTM D 1263-94	Leakage tendencies of automotive wheel bearing greases
ASTM D 1264-96	Water washout characteristics
ASTM D 1478-91	Low-temperature torque of ball bearing greases
ASTM D 1742-88	Oil separation during storage (air pressure method)
ASTM D 1743-94	Corrosion preventive properties
ASTM D 1831-88	Roll stability
ASTM D 2509-93	Load carrying capacity, Timken method
ASTM D 3337-94	Life and torque in small bearings
ASTM D 3527-95	Life performance of automotive wheel bearing greases
ASTM D 4049-86	Resistance to water spray

14.7. Grease Rheology (see Chap. 3)

Because of their complex rheological properties [433] greases have been described as both solid and liquid or as viscoelastic plastic solids [434]. Beyond the yield point, where flow occurs under stress, greases have an apparent viscosity which depends on shear rate, temperature, and shear time, and, to some extent, even on the mechanical pretreatment. This can be explained in simple terms, as, for example, in the NLGI Lubricating Grease Guide [435]. However, when the mathematical background of plastic flow according to

Bingham, pseudoplastic flow according to Ostwald, and liquid flow according to Newton is taken into account the subject [436], [437], a very sophisticated treatment is necessary [438]. Controlled stress rheometers seem to be the best suited devices for a better insight into grease rheology today [439] but will maybe be assisted by velocity imaging nNMR spectrometers in the near future [440].

It cannot surprise that the thickener has some influence on the rheological properties of a grease [441]. Of all the thickeners compared varieties of highly dispersed silica seem to respond best rheologically to both low and high temperatures [442]. For a series of military greases a quasi linear relationship was observed between apparent viscosity and low-temperature torque [443]. With perfluorinated polyethers thickened with PTFE it was possible to show correlation between rheological and lubrication properties [444].

New attempts to gain deeper insight into the dynamic behavior of greases include the examination of possible chaotic states [445], the observation of temperature-related changes with the aid of refractive index measurements [446], and the consideration of rheological wear [447] or the change of the storage modulus of a grease under stress [448].

14.8. Performance

The performance of a grease is, again, probably best judged in terms of the thickener [449]. From a more theoretical view there are twelve main phenomena which must be considered. Of these twelve, all but two – tackiness and toxicity – are related either to pressure or to temperature. The action or effect of pressure or temperature result in 24 requirements (Table 45). It is out of question for a real grease to satisfy all these requirements. The suitability of a grease for both high- and low-temperature applications is, for example, difficult to achieve, although the lower and upper temperature limits of a grease exceed those of its base oil, by analogy with Raoult's law. This means that the thickener acts as an impurity that, on the one hand, hinders crystallization and thus lowers the pour point of the oil yet, on the other hand, reduces its vapor pressure. The effect can be increased by use of the kinds of polymer employed as pour point depressants and viscosity index improvers in lubricating oils. The temperature-dependence of the apparent viscosity of a grease – at constant shear rates – is less pronounced than that of its base oil.

Table 47. Important DIN (ASTM) test methods for lubricating greases.

DIN 51350-4	(ASTM D 2596-97)
Testing in the Shell four-ball tester, determination of the welding load of consistent lubricants	
DIN 51350-5	(ASTM D 2266-91)
Testing in the Shell four-ball tester, determination of the wear parameters of consistent lubricants	
DIN 51801	(ASTM D 566-97), replaced by DIN ISO 2176
Determination of dropping point of greases	
DIN 51802	
Testing of roller bearing greases with regard to their corrosion-inhibiting properties, SKF-Emcor method	
DIN 51804-1	(ASTM D 217-97), replaced by DIN ISO 2137
Determination of cone penetration of greases with hollow cone and solid cone	
DIN 51804-2	(ASTM D 1403-97), replaced by DIN ISO 2137
Determination of cone penetration of greases with one-quarter cone	
DIN 51805	
Determination of yield pressure of lubricating greases, Kesternich-method	
DIN 51807-1	
Test for the behavior of greases in the presence of water, static test	
DIN 51808	(ASTM D 942-90)
Determination of oxidation stability of greases, oxygen method	
DIN 51810	
Determination of flow behaviour of greases in the rotary viscometer	
DIN 51811	(ASTM D 4048-86)
Testing of corrosive effects of greases on copper, copper strip test	
DIN 51817	
Determination of oil separation from greases under static conditions	
DIN 51821-2	
Test using the FAG roller bearing grease testing apparatus FE 9	

14.8.1. Test Methods

Many test methods are used today; all are meant to judge the single or combined and more or less complex properties of greases. The most important ASTM and DIN methods are described in Tables 46 and 47. Complete collections are published regularly [451], [452], the same is true for the French AFNOR, the English IP, the Japanese JIS, and some other national collections. A description of Russian GOST and former East German TGL methods is given in [450]. The devel-

opment of international standards (EN and ISO) is slowly proceeding.

The methods themselves are described in Chapter 16.

14.8.2. Analytical Methods

Elemental analysis of greases is nowadays performed by spectroscopic methods, e.g., X-ray fluorescence spectrometry (XRF), inductively coupled plasma atomic emission (ICP), or atomic absorption spectrometry (AAS) [453], with attention being directed mostly to methods of preparation [454], [455]. IR spectroscopy was introduced as a means of identifying greases and their components ca 40 years ago [456–458]. Its use has steadily grown since and been extended to questions of structure, development, and manufacture also [459]. NMR has also been used to investigate structural questions [460] and electron microscopy has enabled not only the scrutiny of soap fibers [461] but also study of thermal changes in greases [462].

The use of thermogravimetry (TG) is usually limited to investigations of base oils [463], but the other thermoanalytical method, differential scanning calorimetry (DSC) [464], [465], or a combination of both, is expected to become a valuable tool in the analysis of grease and antioxidant analysis.

Chromatographic methods, e.g., gas (GC) and high-pressure liquid chromatography (HPLC), are mainly used to identify the components of liquid or liquefied grease [466], [467].

14.9. Applications

The selection of a grease for a particular application is always a compromise between the demands of a customer and the circumstances the grease must face during its operational life – temperature, speed, load including centrifugal forces and vibrations, and relubrication intervals.

14.9.1. Roller Bearings

The servie life of roller bearings is connected with that of the grease used, especially under extreme conditions [468]. Sophisticated test equipment has been developed, mainly to ensure better lifetime predictability for the selected bearing together with the selected grease [469], [470]. The test rigs SKF R2F and later FAG FE 9 have found great acceptance in Germany [471], [472].

Clean production and low-noise greases are meeting reliability and lifetime requirements of roller bearings. The stringent requirements of high-precision bearings, for small bearings in video and audio applications, and bearings for military use have been established for years [473], [474].

In general greases used in roller bearings such as ball-, deep groove ball-, thrust ball-, spherical-, taper-, cylindrical- or needle roller bearings must have good working stability. This can be checked by the prolonged penetration test and the Shell-roller test (ASTM 1831) [475]. Conventional lithium greases in the NLGI class 2 are recommended for most types of bearing at working temperatures up to 120 °C. Greases of the NLGI class 1 are preferred for needle bearings. For bearings exposed to temperatures above 120 °C complex soap or polyurea thickened greases are preferable. For bearings that must operate under high load and/or low speed the base oil viscosity must be 200 mm/s^2 minimum at 40 °C. Greases for cold climates or for aerospace or military use have to ensure performance down to below −70 °C. Low-temperature performance can be checked with the low-temperature torque (ASTM 1263), the low-temperature penetration (AFNOR NF T 60-171) and the flow pressure (DIN 51805) tests [476–478]. Greases of that kind need base oils with sufficiently low pour points. In many military applications long-life properties are also required; these can be fulfilled by use of synthetic base oils only [479]

Because plain bearings are often exposed to moisture or water, calcium soap-thickened greases are recommended. When open housings are used in a dusty atmosphere frequent relubrication makes it possible to wash out the contaminated grease.

Relubrication Intervals. The lubrication interval t_f is based on the F_{10} value of a standard grease as agreed in DIN 51 825 [480] under normal environmental conditions with temperatures up to 70 °C and a mean bearing load of

$P/C < 0.1$. Figure 58 and Table 48 takes into consideration the type of bearing and the speed. For each 15 K temperature increase the relubrication interval is said to be reduced by 50 %. Severe working conditions reduce the lubrication interval t_f to a reduced lubrication interval t_{fq}.

$$t_{fq} = f_1 \times f_2 \times f_3 \times f_4 \times f_5 \times t_f \quad (16.1)$$

Table 48. Relationship between bearing type and correction factors for relubrication intervals (GFT Worksheet 3)

Bearing type		k_f
Deep grove ball bearings	single row	0.9–1.1
	double row	1.5
Angular contact ball bearings	single row	1.6
	double row	2
Spindle bearings	$\alpha = 15°$	0.75
	$\alpha = 25°$	0.9
Four point bearings		1.6
Self-aligning ball bearings		1.3–1.6
Thrust ball bearings		5–6
Angular contact thrust ball bearings	double row	1.4
Cylinder roller bearings	single row	3–3.5[a]
	double row	3.5
	full complement	25
Cylindrical roller thrust bearings		90
Needle roller bearings		3.5
Tapered roller bearings		4
Barrel roller bearings		10
Spherical roller bearings without lips (E-design)		7–9
Spherical roller bearings with center lip		9–12

[a] $k_f = 2$ for radial load or increasing thrust load and $k_f = 3$ for constant thrust load.

In relubrication it is usually impossible to remove the used grease. Consequently the relubrication interval t_{fq} must to be reduced by 30 to 50 %.

14.9.2. Cars, Trucks, Construction Vehicles

Most modern cars do not need relubrication, with the exception of door hinges, lock mechanisms, and battery poles. But among the approximately 30 hidden greases (Fig. 59) in a modern car [481], [482] only the constant-velocity (CV) joint greases are required in substantial quantities. Although improved conventional lithium greases containing molybdenum disulfide are still in use [483], lithium complex or polyurea greases are already preferred in some modern cars and this usage will increase in the future [484]. Most of the greases used in cars, for example the greases for CV joints, hub units, starters, alternators, seat adjustments, clutches release bearings, belt – pulley bearings, window levers and windshield wiper gears, are specified and approved by the large motor companies and developed in close cooperation with the grease manufacturers. For the same application, however, different motor companies have different grease specifications and approvals; for example, most European and U.S. motor companies prefer lithium complex greases in the front wheel bearings, whereas Japanese manufacturers prefer polyurea greases.

ASTM D 4950 (see below) describe the minimum requirements of current greases in automotive service – fill applications for passenger cars, trucks, and other vehicles operating under various service conditions [485].

Chassis grease classifications – intended use of chassis (L) classified greases:

LA Classification
Chassis components and universal joints under mild duty
- Frequent relubrication
- Noncritical applications

LB Classification
Chassis components and universal joints under mild to severe duty
- Prolonged relubrication intervals
- High loads
- Severe vibration
- Exposure to water or other contaminants

Intended use of wheel bearing (G) classified greases:

GA Classification
Service typical of wheel bearings operating under mild duty
- Frequent relubrication
- Non-critical applications

GB Classification
Service typical of wheel bearings operating under mild duty/moderate duty
- Normal urban, highway and off-highway service

GC Classification

Figure 58. Re-lubrication intervals

Figure 59. Greases hidden in a modern car

Service typical of wheel bearings operating under mild duty/severe duty
- High bearing temperatures
- Frequent stop and go service (buses, taxis, police)
- Severe braking service (trailer towing, heavy towing, mountain driving)

Lithium-based multipurpose greases have replaced several other greases for the relubrication of trucks and construction equipment. Conventional lithium soap based greases that require frequent relubrication are still in use for the wheel bearings of trucks and trailers. Modern trucks and trailers with prolonged oil-drain intervals require lithium complex greases with semisynthetic or fully synthetic base oils. Lithium greases containing black solid lubricants are recommended for 5th-wheel applica-

tions, for chassis points, and for plain bearings of construction equipment. Many trucks and buses and much construction equipment uses centralized lubricating systems, designed for semifluid greases of NLGI-class 00 or 000, for onboard relubrication. Other systems require greases of NLGI class 2. Lithium greases optimized for low temperature applications, good pumpability, and low oil separation are recommended.

14.9.3. Steel Mills

In Europe calcium complex and sometimes polyurea greases based on mineral oil are used for lubricating continuous casting equipment. The U.S. market prefers aluminum complex and polyurea greases and Japanese equipment manufacturers mainly recommend polyurea greases. Some roller bearing manufacturers equip continuous castings with double- or triple-sealed bearings that are greased for life, preferably with synthetic polyurea greases. When the sealing of the bearings is not perfect relubrication has a cleaning function. Contaminated grease that could result in limited lifetime is squeezed out.

Conventional EP lithium greases, calcium complex greases, calcium sulfonate complex greases, lithium complex greases, and aluminum complex greases, all based on mineral oils are used in hot rolling equipment. Most customers require a minimum base oil viscosity of 200 mm/s^2 at 40 °C [486]. The rotating shift system is typically used for hot-rolling lubrication. In general the bearings are not regreased during operation, only during maintenance.

Many different greases, e.g., conventional EP lithium greases, lithium complex greases, calcium complex greases, and calcium sulfonate complex greases, all based on mineral oil, are used in cold rolling equipment. Modern greases use a lithium – calcium mixed soap for improved water resistance.

14.9.4. Mining

Open pit mines which use wheel bucket excavators and belt systems to ship the spoil and coal are especially large grease consumers. Lithium or lithium – calcium mixed-soap-based grease with base oil viscosities > 350 mm/s^2 at 40 °C and an effective EP and AW additive package are used. Black solid lubricants are also recommended. Because the equipment is exposed to dust or water and mud, the sealing efficiency of the bearings determines their lifetime and must be supported by a grease.

Kilometers of wire rope are used on the excavators or drag lines and in the underground mines. During production of the wire ropes lubricants are applied to ensure corrosion protection and to minimize friction of the single wires when the rope stretches under load.

Lay-up lubricants based on wax resin are applied during manufacture to ensure lubrication of the individual wires and stands.

During operation in some countries the wire ropes are maintained by cleaning the surface and relubrication. In many countries bitumen-based products are still in use, but are being replaced by bitumen-free greases or even biodegradable lubricants.

Winch greases, preferable lithium complex greases with improved water-resistance, ensure prolonged winch lifetimes up to several years.

14.9.5. Railroad, Railway

Depending on the design of the driving system of the locomotive a gear oil or a gear grease is required. The poor sealing properties of these kind of gears leads usually to leakage; this is usually minimized by use of bitumen-based products. Modern greases are thickened with lithium or sodium soap and based on mineral oils of up to 2000 mm/s^2 at 40 °C. Traction motor gear greases are not described in terms of consistency; the apparent viscosity is usually checked with a Brookfield viscometer, for example with a number 3 spindle at 93 °C and at 4 rpm and giving results of 5000 to 10 000 mPa · s [487].

The axle bearings are greased with conventional lithium EP greases. The development of ready-to-build in axle boxes and the increasing speed of modern trains have led to improvement of the high-temperature performance and lifetime of greases.

Switch lubrication, wheel flange lubrication (mainly used in Europe), and rail track-side lubrication in curves, used mainly in the USA and Canada, cause environmental problems. For these applications biodegradable greases based

on esters have better wear-protection and consumption performance as conventional greases [488–490]. These greases must be sprayable because of the means of application.

14.9.6. Gears

Fibrous sodium soap greases of NLGI-class 0, 00, or even 000 consistency are used. Although the load-carrying capacity, antiwear properties, and adhesion of these greases is especially good, lithium-based greases and greases based on synthetic hydrocarbons or polyglycols are gaining in importance

Girth gear drives are a type of drive widely used for many large systems in the primary industries [491]. These open gears require an adhesive grease based on high-viscosity oils. Such greases are usually sprayed on the teeth by means of a centralized lubricating system.

14.9.7. Food-Grade Applications

Greases for lubricating machines used in food processing must fulfil specific requirements relating to food legislation, human health protection, taste, and odor. These properties must be approved by internationally accepted tests and organizations [492].

The FDA lists ingredients permitted for use in food-grade grease formulations (21 CFR §178.3570); white oils are listed in 21 CFR §178.3620. The USDA (United States Department of Agriculture) has approved the finished products. For white and synthetic oil-based products maximum contamination of 0.1 g/kg food is allowed. Since USDA stopped ist activities in 1999 a working group of ELGI, NLGI and the European Hygienic Equipment Design Group (EHEDG) was founded with the aim to install an ISO Standard for food grade lubricants.

14.9.8. Textile Machines

Because greases could contaminate textiles, they are formulated with white oils and thickened with water-soluble sodium soaps, and are thus removable by washing.

14.9.9. Applications with Polymeric Materials

There are three ways in which greases and polymeric materials can come into contact: polymers can be contained in greases as thickeners, as solid lubricants, and as additives; they can act as sealants; and they can form one or even both of the solid partners in friction couples. Although base oils are the primary consideration [493], when the interaction of greases with sealants is important [494], [495] – the influence of additives, and among these especially EP additives, must always be considered [496]. Even migration of soap molecules into a polymer can occur [497].

An early test method for the action of lubricants on polymeric materials was the pendulum according to Barker [498]. During the automation of this process a more meaningful friction and wear tester was developed [499], [500]. It proved also to be necessary to test the tendency of a polymer to form cracks under the influence of its lubricant and tension [501].

The lubrication of polymers or polymers and metals as friction couples is one field in which silicone greases and, better, fluorinated silicone greases, or, even better, greases based on perfluoropolyalkyl ethers are of some advantage. Although silicone greases made with highly dispersed silicic acid should be used as general lubricants and as sealants [502], silicone greases made with the usual thickeners are sometimes preferable to other synthetic greases. With calcium stearate or 12-hydroxystearate, for example, they are permitted in food applications [503].

14.10. Ecology and the Environment

Pre-industrial greases consisted of tallow or vegetable oils and their reaction products with lime; they were therefore, not merely ecologically compatible lubricants, but even rapidly biodegradable. When mineral oils took over, most of the thickeners and some of the additives remained ecologically acceptable. The ecological and environmental aspects of modern base oils have been described in detail in Chapter 7. Of all the vegetable oils that could

be chosen as base oils for greases, in Central Europe only rape seed oil has been introduced on a technical scale [504] and only for loss-lubrication applications. Initially calcium 12-hydroxystearate was chosen as the most suitable thickener [505]. Greases of that kind proved superior to lithium- and mineral oil-based general-purpose grades (Fig. 60). The limitations of vegetable oil-based greases soon led to the introduction of transesterified vegetable oils [506] and synthetic esters (see Chap. 5). Because of industrial demands greases based on calcium 12-hydroxystearate were soon replaced by lithium and lithium – calcium greases [507–509]. Polyurea greases [510], aluminum complex greases [511], and titanium complex greases [512] followed.

Figure 60. Friction – load behavior of rapeseed oil-based calcium 12-hydroxystearate greases

The biodegradability of greases essentially reflects the biodegradability of their base oils. In round robin tests greases based on rape seed oil and calcium 12-hydroxystearate achieved biodegradability close to 100 %. Methods enabling the use of emulsifiers led to significantly lower results [513].

The elimination of toxic components such as polycyclic hydrocarbons from base oils is almost complete. This is also true for chlorine substitution. The substitution of antimony and lead cations and nitrite anions in additives is not yet complete, because it is not easy to maintain the same performance level. In Germany the demand for environmentally harmless products [514] became an additional aspect of the performance of greases; changes in the demands for water pollution class (WGK) 0, that came into force in 1999 aggravated the situation. The most suitable antioxidants are only accepted in concentrations which are too low, hydrocarbons including polyalphaolefins, white oils, and low-viscosity polybutenes are not accepted and the most suitable soaps are also excluded.

Although experiences with biodegradable greases are promising [515], [516], some problems, mainly relating to legal aspects of waste management [517] and the balance between ecological requirements and economical possibilities [518], remain unsolved. Therefore the third and possibly most important aspect of applying greases in a manner that is both environmentally responsible and economical is to minimize the amount of lubricant necessary and to maximize lifetime by using the most inert materials [519], [520].

14.11. Grease Tribology

General aspects of friction and wear [521], and of lubricating oils and their viscosity [522], have been described in detail in Chapters 2 and 3. Recent tribological research on greases has dealt with the time-dependence of their behavior under stress as a fourth factor in addition to temperature, pressure, and thickener properties [523]. Behavior in EHL contacts, where the thickness of grease films can exceed that of their base oil under comparable conditions [524], [525], and the behavior under starved conditions, when the load is supposed to be carried by thickener particles deposited in the center of the contact [526], has also been of concern. Soap deterioration is another important subject [527], [528].

15. Solid Lubricants

Solid lubricants are required for lubrication under extreme conditions where the bearing surfaces in tribological contact must still be effectively separated. The life of lubricated machine parts depends on the functional and tribological design and optimization of lubricants as calculable functional elements. To make a systematic

choice of a suitable lubricant it is absolutely necessary to understand the relationship between friction, wear, and lubrication and the interaction between the elements of the tribological system and the specific properties of each element.

Special attention must be given to the different stress factors and the structure of the tribological system (see Chap. 2).

Products containing solid lubricants are often used to solve problems, particularly in boundary and mixed frictional states when high specific loads are applied to sliding surfaces and at very low hydrodynamically effective speeds but also in critical applications where, e.g., the lubricant must perform over a wide temperature range or under extreme temperature conditions, for example in aviation and in rocket technology.

Dry lubrication with solid lubricants is also required in nuclear reactors, in high vacuum applications, in aggressive environments, and in applications where contamination by lubricating oils or greases cannot be tolerated.

Table 49. Structural lubricants.

Name	Formula
Graphite	C
Graphite fluoride	$(CF_x)_n$
Molybdenum disulfide	MoS_2
Molybdenum diselenide	$MoSe_2$
Tungsten disulfide	WS_2
Tungsten diselenide	WSe_2
Niobium disulfide	NbS_2
Niobium diselenide	$NbSe_2$
Tantalum disulfide	TaS_2
Tantalum diselenide	$TaSe_2$
Titanium disulfide	TiS_2
Titanium diselenide	$TiSe_2$
Titanium telluride	$TiTe_2$
Cerium fluoride	CeF_3
Barium hydroxide	$Ba(OH)_2$
Cadmium chloride	$CdCl_2$
Cobalt chloride	$CoCl_2$
Zirconium chloride	$ZrCl_2$
Lead chloride	$PbCl_2$
Lead iodide	PbI_2
Boron nitride	BN
Silver sulfate	Ag_2SO_4
Borax	$Na_2B_4O_7$
Talc	$Mg_3(OH)_2Si_2O_{10}$
Mica	$KAl_2(Si_3Al)O_{10}(OH)_2$

15.1. Classification

A solid lubricant is often defined as any solid material which reduces friction and/or wear of contacting surfaces in relative motion. Various systems are used to classify the different types of solid lubricant. An arbitrary, but useful, classification is into structural lubricants, mechanical lubricants, soaps, and chemically active lubricants.

15.1.1. Class 1: Structural Lubricants

The most widely used solid lubricants are graphite and molybdenum disulfide. Their satisfactory lubricating properties are assumed to result from their layered lattice structures. In addition to these two substances, other solids are used, for example metal halides and sulfides, which have, in the main, inherent lubricant properties, a lamellar hexagonal crystal structure, and are usually anisotropic (Table 49).

In contrast to graphite and molybdenum disulfide these are not yet extensively used in industry.

15.1.2. Class 2: Mechanical Lubricants

There are different types of substances within this class whose lubricating effect is based on different physical and mechanical properties or special conditions. These lubricants are divided into self-lubricating substances, substances that need a supporting medium to create lubricating properties, and substances with indirect lubricating properties based on their hardness.

Self-Lubricating substances can be classified as organic compounds, metal films, chemical surface layers, and glasses.

Organic Compounds. The most important self-lubricating organic substances are liste below:

Linear polymers (thermoplastic types)
Poly(tetrafluoroethylene) (PTFE)
Fluoroethylene – propene (FEP) copolymers
Perfluoroalkoxy polymers (PFA)
Polyethylene (PE)
Polypropylene (PP)
Polyurethane (PU)
Polyamide
Polyacetals

Polyterephthalate
Polysiloxanes
Nylon
Cross-linked polymers (thermosetting types)
  Phenol – formaldehyde resin
  Urea – melamine – formaldehyde resin
  Epoxy resin
  Phenolic resin
  Unsaturated polyester resin
Polyimides

The sliding characteristics of polymers depend on their chemical nature and the mating partner. The permissible load is a function of heat dissipation. Temperature changes have little influence on the friction characteristics of polymers. Addition of MoS_2, graphite, and metal powder improves the frictional characteristics of the polymers and increases their hardness. Graphite also increases the elasticity module of PTFE.

Metal Films. Important self-lubricating metal films include:

Lead
Tin
Silver
Indium
Barium
Gold
Aluminum
Nickel (Ni and Ni – Cr alloys)
Copper (Cu and Cu alloys)
Zinc (Zn and Zn alloys)

Friction can be reduced by the coating of the body material surfaces with a thin film of a soft metal, because the friction depends on the shear strength of the soft metal film. The durability depends on the film hardness, homogeneity, and adhesion. The lubricating effect of soft metal layers is limited by their melting point.

Chemical Surface Layers (Conversion Films). In addition to the naturally occurring oxide films present on the surface of most base materials exposed to air, other solid lubricant films can be formed by chemical or electrochemical action on the metal surface.

Chemical surface coatings such as zinc, iron, or manganese phosphates behave similarly to soft metal coatings but consist not of a metal but of metal salts. Bonderization (phosphate treatment) creates a thin, microcrystalline, strongly adhering phosphate layer on the metal surface; this reduces the coefficient of friction and the danger of seizure during the running-in period. The lubricating efficiency of the layer, which is normally 2–5 µm thick, is based on its lower shear strength in comparison with the metal.

Glasses (→ Glass). The lubrication properties of glass depend on the composition. The coefficient of friction at a given temperature is a function of the viscosity, the thermal conductivity, the rate of shear, the area of shear, the capacity to dissolve different amounts of oxide from the surface of the material to be lubricated, and the contact angle between the glass and the material, because this determines the capacity of the glass to wet the material.

The importance of glasses used as lubricants is specially to be seen in metal-forming operations with operating temperatures up to ca. 1500 °C.

Substances with lubricating properties that need a supporting medium can be classified as inorganic compounds and metal powders.

Inorganic Compounds (Table 50). The coefficient of friction of natural oxide films on metals, which are usually approx. 10 nm thick, has been investigated. It is generally accepted that the oxide film reduces surface damage, makes sliding smooth, and often reduces friction.

Table 50. Inorganic compounds needing a supporting medium

Metal sulfides	ZnS, SnS_2, FeS, ...
Metal fluorides	CaF_2, LiF, ...
Metal phosphates	$Zn_2P_2O_7$, $Ca_3(PO_4)_2$, $Fe_2P_2O_7$, ...
Metal hydroxides	$Ca(OH)_2$, $Mg(OH)_2$, $Zn(OH)_2$, ...
Metal oxides	PbO, ZnO, FeO, Fe_2O_3, ...

Sulfides, fluorides, phosphates and hydroxides are claimed to act as a supporting agent or a catalyst by producing friction- and wear-reducing layers. Calcium hydroxide, for example, supports the production of a layer of Fe_3O_4 iron oxide on the rubbing surface of steel.

The process of formation of these layers depends on the chemical composition of steel and, in particular, on its surface chemistry.

Phosphate layers, by galvanic techniques, are mainly used as precoatings for dry-film application and as lubricant carriers in cold metal-forming processes. In addition to acting as a lubricant carrier, the phosphate coating can be

plastically deformed with the steel slug and, therefore, in conjunction with the lubricant, prevents metal – metal contact and thus reduces surface friction and wear.

The three main types of phosphating solutions contain zinc, iron, and manganese phosphates, and of these the zinc phosphate is probably the most widely used.

Metal Powders. In contrast to structural lubricants and self-lubricating mechanical lubricants, the lubricating properties of the other mechanical lubricants are mainly based on the supporting effect of a carrier substance or a binder. The main purpose of these substances, which include Pb, Sn, Zn, Cu, Ag, and In, is to improve the adhesion and cohesion properties of the non-self-lubricating mechanical lubricants.

Substances with Indirect Lubricating Properties Based on their Hardness (Physical Vapor Deposition, Chemical Vapor Deposition, and Diamond-like Carbon Layers). Vapor-deposited (VD) coatings of oxides, borides, nitrides, or silicates, for example TiN, TiNC, CrN, ZrN, and AlTiN, usually have quite high coefficients of friction but can prevent seizure even at high temperature and offer excellent wear resistance.

Another relatively new form of thin-film layer with proven good tribological properties is diamond-like amorphous carbon (DLC) (→ Thin Films, Chap. 2.3.). Hardness values for DLC range from 500 to 13 000 HV depending on the amount of hydrogenation, from 50 % to zero. In addition to hard coatings there are also soft physical vapor-deposition coatings containing MoS_2 or MoS_2 – metal composites. These films, normally deposited by various sputtering technologies like ion-beam-assisted deposition (IBAD) or closed-field-magnetron sputtering (CFMS), afford excellent tribological properties in terms of wear-resistance and low coefficient of friction. They are used for cutting and forming tools, ball bearings, and sliding contacts with steel and ceramics.

15.1.3. Class 3: Soaps

Soaps often give the lowest coefficients of friction obtainable with solid lubricants but in general cannot be used above their melting points or at high loads.

The main function of soaps in lubrication technology is in the preparation of greases (see Chap. 14). The main use of soaps as lubricants in their own right depends on their formation in situ on a metal surface, by the chemical attack of a fatty acid on the metal.

15.1.4. Class 4: Chemically Active Lubricants

This category includes EP and AW additives and a variety of chemicals which interact with the metal surface to produce a lubricating or protecting layer (see Chap. 6).

15.2. Characteristics

15.2.1. Crystal Structures of Lamellar Solid Lubricants

Graphite (→ Carbon, Chap. 3.1.). In the hexagonal graphite structure each carbon atom is linked to its nearest neighbors by sp^2 type σ bonds. The strength of the latter is increased above the normal single covalent C – C bond by the interaction of non-localized electrons associated with the $2p_z$ orbital of the planar carbon atoms. It is this extra bonding which gives graphite its thermal stability. The planes themselves are held together largely by van der Waals forces which are much weaker than the planar bonding forces and the strength of bonding to a substrate.

The low friction of graphite is not based solely on its crystal structure. It also depends on adsorbed films, particularly of water vapor, which provide surfaces with low cohesion. Thus, graphite develops its most favorable lubricating properties in the presence of moisture.

Molybdenum Disulfide (→ Molybdenum and Molybdenum Compounds, Chap. 7.3.). The crystal of molybdenum disulfide has a hexagonal structure with trigonal symmetry. Each Mo atom is surrounded by a trigonal prism of sulfur atoms.

The lubricating effect of MoS_2 is also based on its crystal structure. The weak bonds (van der Waals forces) between the sulfur layers enable

easy movement of the lamellae over each other, resulting in a low friction between the sliding parts. On the other hand, the ionic bond between Mo and S gives the layers a high strength so that they can resist the penetration of surface asperities.

15.2.2. Heat Stability

Heat stability is required if thermal decomposition of the solid lubricants is to be avoided, especially in the presence of oxygen-, carbon dioxide-, or water-containing atmospheres. Very often the decomposition products are either corrosive vapors or abrasive solids.

When heated in air, graphite forms carbon dioxide above 450 °C; this escapes without leaving any grinding particles behind. MoS_2 is attacked by oxygen even at 20 °C. In air, appreciable oxidation to molybdenum trioxide occurs above 400 °C and effects the lubricating properties and the adhesion of MoS_2 to metal surfaces. When oxidation can be excluded, MoS_2 retains its lubricating properties up to 800 °C. Lead monoxide is an excellent lubricant up to 700 °C. Metal-free phthalocyanines have been established as very efficient lubricants up to temperatures of 800–900 °C. Glass has proved to be an efficient lubricant at extreme loads and temperatures up to 1200 °C.

Other solids, for example metal oxides, sulfides or phosphates, also afford excellent heat stability. Without a supporting liquid, however, these solids provide no lubricating properties but build up separating layers only. The lubrication effect is, therefore, limited by the heat stability of the carrying substance.

The melting point of a solid lubricant can be regarded as a physical aspect of heat stability.

15.2.3. Thermal Conductivity

Frictional heat, developed by rubbing of material surfaces at the high spots, is also transmitted to the solid lubricant, which must be capable of dissipating this heat as quickly as possible – or local welding of the material might occur, despite the presence of the solid. This is particularly true of plastic solid lubricants, which all have poor thermal conductivity.

15.2.4. Adsorbed Films

Adsorbed film of gas or vapor might be attached to the external surface of the solid or chemically to an internal surface (intercalation). Physically or chemically adsorbed molecules on the external surface of the solid can influence:

- The sintering of the aggregates of the particles under the action of heat;
- The ease of breakdown of particles under shear stress; and
- The wear properties of the edges of lamellar solids.

The chemisorbed molecules within the particles can affect:

- The decomposition or oxidation temperature of the solid;
- The mechanical properties of the solid; and
- The conductivity (thermal and electrical) of the solid.

15.2.5. Chemical Stability

Chemical stability is closely linked with heat stability. When solid lubricants are to be used intermittently over long periods in relatively inaccessible places, tendency to corrosion can be serious. Corrosion can occur in three ways:

Interaction of the solid with the metal surface;
Action of heat and/or the atmosphere on the solid to give decomposition products, which then react with the metal surface; and
Action of heat and/or the atmosphere on material chemisorbed on to the solid lubricant producing material which has a corrosive action on the metal.

15.2.6. Particle Size

The smaller a nonporous particle, the more active it is. Although such particle activity is required in some applications there are other fields, for example many metal-forming operations, for which it is desirable to have a relatively large particle size range to give the required film properties. With graphite and molybdenum disulfide, relatively coarse particle sizes are advantageous because this results in optimum resistance to oxidation.

15.3. Products Containing Solid Lubricants

15.3.1. Powders

To ensure that solid lubricants in the form of powder give sufficient coverage in a tribological system.

The following requirements must be fulfilled

1) The level of adhesion between the lubricant film and the surface of the material must be great enough to ensure that this lubricant film adheres to this surface when it is subjected to friction.
2) The internal cohesion of the film must be sufficiently large that the film does not split when subjected to friction.
3) The adhesion between the particles and layers in the shearing direction should be as small as possible to keep the resistance to friction low.

These main requirements can be met only by self-lubricating dry lubricants especially by MoS_2 lattice; it is, as a result, the most commonly used. Other solid lubricants which are applied in powder form are organic compounds such as PTFE and graphite, although these fulfil the requirements listed above to a limited extent only.

Before the solid lubricant powder can be applied, the surface of the material must be thoroughly cleaned. Roughing the surface mechanically or with phosphates improves adhesion and therefore the lifetime. The lubricant can be effectively applied by simple rubbing with cloths, sponges, brushes, or polishing pads or polishing buffs, by applying it using suitable carriers, and coating by cathode evaporation in an ultra-high vacuum.

Solid Lubricants in Carrying Media. Most substances used as solid lubricants require a carrying medium, a bonding agent and/or pretreatment of the material surface, to help create, or improve, their adhesive and film-creating properties. The substances used as bonding agents are: organic binding agents, resins; inorganic binding agents, silicates; and oils, greases, water.

It is also advantageous to pretreat the surfaces by: degreasing; sandblasting, corroding, etching; phosphating, anodizing; and activating (e.g., low-pressure plasma).

15.3.2. Dispersions and Suspensions

Dispersions and suspensions in carrying liquids with low volatility are mainly used in areas in which, for tribological reasons, a dry lubricating film should be created, but where effective application of a powder is not possible for technical reasons. The same types of solid lubricant are used here in the same way as for powders.

Dispersions and suspensions of solid lubricants in water are usually used to coat mass elements for cold and hot forming. The most commonly used substances here are salts, special white solid lubricants, and graphite.

Dispersions and suspensions in oils also act as aids in forming techniques, and they are also used as additions in gear- and oil-lubricating systems. The solid lubricants used here in forming techniques are the same types as those used as dispersions and suspensions in water. MoS_2 plays a dominant role as an additive to lubricating gears and for general use in oil lubricating systems.

15.3.3. Greases and Grease Pastes

Addition of solid lubricants to greases is primarily intended to have a positive effect on their capacity to absorb pressure, and the ability to withstand wear and tear, and friction. The specific advantages of solid lubricants in comparison with oil-soluble, chemically reactive additives is that they react neutrally to many types of plastic and elastomer, perform well at high temperatures and have good safety reserves with regard to emergency running properties, which come into action when the layer of grease collapses. The use of black solid lubricants such as graphite and MoS_2 also have a beneficial effect on running-in processes and the capacity to withstand wear and tear in boundary and mixed friction areas. Where oscillating movements or vibration is involved, white solid lubricants have the advantage. These effects are illustrated in Figs. 61 and 62.

Solid lubricants in greases are used at concentrations of 1–3 %. When this proportion rises to

Figure 61. Lithium grease with molybdenum disulfide, showing the irregular pattern of the wear profile, the chipping of the material, and serious wear. The maximum wear depth exceeds 13 µm

over 10 % they are known as grease pastes, because the solid lubricant at this concentration has a noticeable thickening effect.

High-performance lubricating greases usually contain combinations of two or more substances, which have a synergistic effect. This applies both to the combination of graphite and MoS_2 and to mixtures of different inorganic solid lubricating substances, for example calcium hydroxide, zinc phosphate, or iron sulfide.

15.3.4. Pastes

Pastes are solid lubricants in a carrying oil. To achieve the correct consistency, the proportion of solid lubricant must be at least 40 %. To reduce the undesirable 'bleeding' effect, modern formulations often include a small amount of soap.

Black pastes usually contain graphite or MoS_2 and combinations of both. Because of their high load-bearing capacity, these pastes are particularly useful when movement with very slow relative speeds is involved, e.g., assembly processes, and running-in processes.

Pastes prepared from combinations of white solid lubricants are especially suitable for use where oscillating movements or vibration is involved. White pastes are particularly good at preventing the wear and tear which results from vibration and are proven to afford excellent protection against fretting corrosion.

Another area where pastes are traditionally used is for lubrication of screw connections. Special screws made of steels which are resistant to high temperatures, based on chrome/nickel alloys, are prone to seizure because an oxide layer is not created.

The pastes used in this particular application area are usually made up of combinations of solid lubricants and special metal powders. More recent developments show that the use of formulations which do not contain metal, and are based on white solid lubricants, perform well when used at high temperatures.

Figure 62. Lithium grease with white solid lubricants showing the smooth pattern of the wear profile. The maximum wear depth is only 5.9 µm, the wear pattern is uniform, and there is no chipping of material. Scanning electron photomicrographs (50 × magnification).

15.3.5. Dry-Film Lubricants

Lubricating varnishes or dry-film lubricants are suspensions of solid lubricants and other additives in a solution of inorganic or organic binding agents. The most commonly used solid lubricants are MoS_2, graphite and PTFE. The most important additives are pigments which protect against corrosion. The main types of binding agent used are organic resins (acrylic, phenol, epoxy, silicone, urethane), cellulose, and inorganic silicates and phosphates. Hydrocarbons or water are used as solvents. Dry-film lubricants can be used in a variety of ways; these depend primarily on the number, shape, and/or particular requirements with regard to partial coating. They are applied by dipping centrifuges and drums and by various types of spraying procedure. The hardening process depends on the type of binding system and happens at ambient temperature or in an enameling stove. After they have hardened lubricating varnishes form a highly adhesive, dry film of lubricant. The proportion of solid lubricants in the layer created in this way can be as high as 70 %.

Solid lubricants with a layer structure (MoS_2) have a floating effect in the wet film, whereby the layers arrange themselves horizontally as the film dries and settle on top of each other in individual layers. This is how a separating layer is created between the base unit and the opposing unit of the tribological system. In an ideal situation this layer is between 10 and 15 µm thick. When placed under pressure, the texture of this layer becomes compressed and creates an extremely smooth, shiny film surface. PTFE lubricating varnishes are usually applied in much thinner layers, e.g., 3 to 5 µm thick.

The performance of dry-film lubricants depends on:

1) Their composition, in particular the type of binding agent, the ratio of solid lubricants to the binding agent, the types of solid lubricants, and the film thickness;
2) The properties of the substrate to which the lubricating varnish is applied, in par-

ticular the cleanliness, roughness (porosity; Fig. 63), and hardness of the surface; and

3) Environmental (local) conditions, in particular the demands, placed on the lubricant (e.g., load), the type and speed of movement, the temperature, atmospheric pollution (humidity, dust, radiation), atmospheric pressure, and the surrounding media (gases, liquids).

The pretreatment of the substrate surface plays a particularly important role in the successful use of lubricating varnishes – as already mentioned, the roughness of the surface and the way in which the crystallites are arranged have a considerable impact on their lifetime. Various pretreatment procedures can be used to achieve the best possible surface. Sandblasting, phosphating, anodizing, atramentizing, etching, or corroding are the most suitable for metallic substrates. Plastic and elastomer surfaces can be pretreated by chemical and mechanical processes and by energetic activation procedures.

15.4. Industrial Uses of Products Containing Solid Lubricants

Because of the continuously increasing demands put on modern lubricating systems, almost all formulations contain a certain proportion of solid lubricants. Significant fields of application are the lubrication of machine elements and in process auxiliaries for various production technologies such as, for example, the production of glass or metalworking.

Solid lubricants play a significant role in metalworking, especially in forming. Their main task is to generate an effective separating layer between the tool and the surface of the workpiece and thus act against the adhesion forces between the materials. Solid lubricants, in combination with their carrier medium and other additives, also reduce friction or generate a defined coefficient of friction, and keep the process temperature constant. Through their wear protection function they increase the service life of tools, protect against corrosion, ensure a stipulated surface quality and the accuracy to gage of the workpieces.

Solid lubricants are used in the area of noncutting forming, especially cold and hot forging, pressure die-casting and drawing, and cold extrusion operations.

15.4.1. Screw Lubrication

The machine element most used is the screw. The selection of the most suitable screw lubricant depends upon the material or the surface of the screw and the thread partner, and on the conditions of use, for example temperature, humidity, and the influence of chemicals, radiation, and the constructive requirement according to a stipulated coefficient of friction or minimum pretensioning force, even after the screws have been tightened or loosened many times.

Special high-temperature pastes are used for the lubrication of screw connections at high working temperatures. These pastes comprise a basic oil which is mixed with different solid lubricants and can contain additional additives. In formulation or selection care must be taken to ensure that the components do not contain sulfur, zinc, lead, and aluminum, which can lead to damaging changes to the screw material, e.g., stress crack corrosion at high temperatures. They should also be free of health-hazardous nickel.

Particularly effective in high-temperature applications are greases and pastes combined with white solid lubricant prepared from metal hydroxides, phosphates, and sulfides.

For many screw lubrication applications, special dry-film lubricants are also available as an alternative to greases and pastes. The advantage of lubricating varnish is its simple application in immersion centrifuges or spray drums. The handling of coated screws is clean and suitable for robot systems.

Special areas of application for lubricating varnish and slide films are thread-cutting screws, thread-shaping screws, thread-grooving screws, all kinds of wood screws, and screws made of plastic.

15.4.2. Roller-Bearing Lubrication

For lubrication of roller bearings greases or pastes containing solid lubricants must always be used when reliable separation of the roller body and bearing ring at low speeds and high loads cannot be ensured by grease alone. Over and above this, greases or pastes containing solid

Figure 63. Relative lifetime of MoS_2 solid-film lubricants as a function of surface roughness

lubricants have good emergency running properties and afford high safety under shock and impact stress. Greases or pastes with white solid lubricants are preferable for use in roller bearings employed in oscillating operations. Lubricating varnishes are the best solution for applications in a vacuum, for example, in air and space travel, nuclear engineering, extreme temperatures, or for microsetting movements.

Special constructions also enable solid lubricants to be incorporated in the bearing material; this enables the production of maintenance-free bearings.

15.4.3. Slide Bearing, Slide Guideway, and Slide Surface Lubrication

Here, reliable separation of the material partners must be ensured at all times to comply with the primary demand put on the lubricant for reliable load transfer at lowest wear rates. Whereas, as a general rule, the operating point of a friction bearing is in the region of hydrodynamic lubrication and therefore the viscosity of the lubricant is the most important key value, slide guideways and other slide surfaces (for example, infeed wedges) are mainly in the boundary or mixed friction range. The best solution for these operational requirements is lubrication with PTFE belts and slide liners based on epoxy resin with the incorporation of solid lubricants such as MoS_2, graphite, or polyurethane. Pastes or lubricating varnishes containing solid lubricants are likewise suitable and offer themselves for the running-in phase and the warm-up and cool-down phases in normal operation. In this way the boundary and mixed friction zone can be safely worked through without wear occurring, even with pure oil lubrication, and emergency running properties can be achieved.

15.4.4. Chain Lubrication

When selecting a suitable lubricant special consideration must be given not only to the different chain-drive construction types, but also to the material pairs, the operating parameters, and the ambient conditions. For solid, highly viscous lubrication care must be taken to ensure adequate creep or penetration to get to the narrow gaps, for example, between the bolt and bush. The lubricant must also have an appropriate adhesion capacity so that it is not spun off at high chain speeds or high centrifugal forces at the turning point (pinion and wheel).

15.4.5. Plastic and Elastomer Lubrication

In plastic and elastomer lubrication the material compatibility plays a particularly important role. Swelling, shrinking, or embrittlement are the most serious changes which elastomers can experience when they come into contact with lubricants. Solid lubricants have limited influence on elasticity module, tensile strength, and hardness. On top of reducing friction and protection against wear, the separating effect of the lubricant also plays an important role. The majority of requirement profiles can be covered adequately by lubricating varnishes and films containing solid lubricants.

In plastic lubrication the special features of substances, i.e., interaction between the plastic and the lubricant, must also be taken into consideration. Particular attention must be paid to the tendency to develop stress cracking. Oils, greases and pastes containing solid lubricants, and also lubricating varnishes and slide films, can be used successfully for lubricating plastic and steel, and plastic – plastic pairs. The running-in process must also be given enough attention in the use of plastic materials, and as a general rule, can be positively influenced by solid lubricants.

16. Testing and Analysis

16.1. Base Oil Categories and Evaluation of Various Petroleum Base Oils

The American Petroleum Institute (API) and the Association Technique de l'Industrie Européenne des Lubrifiants (ATIEL) have classified base oils according to their chemical composition. Initially there were four groups; after the introduction of VHVI oils in Europe this was increased to five. The most important reason for these groups was the necessity to regulate base oil interchangeability for engine oils. (Chap. 8). The classification of petroleum base oils (Groups I to III) considers three parameters: saturates content, sulfur content, and viscosity index. Table 4 shows this classification. Accordingly, Group I oils are solvent extracted HVI oils (SN oils), Group II oils are hydrogenated or hydrocracked oils (as the sulfur content of < 300 ppm shows) and Group III products are VHVI oils manufactured by severe hydrocracking and or wax isomerization (VI > 120, sulfur < 300 ppm).

Table 51 shows typical data of various hydrocracked base oils (HC-oils), in comparison with solvent refined oils and polyalphaolefins.

HC-II oils are classified as very high viscosity index (VHVI) oils. HC-III oils are also known as extra or ultra high viscosity index (UHVI) oils. They are generally made by hydrocracking and isomerization slack waxes followed by solvent dewaxing.

Table 52 shows typical hydrocarbon compositions of HC oils in comparison with conventional solvent refined oils and polyalphaolefins [64].

HC-II and HC-III oils are being increasingly compared with synthetic polyalphaolefins (PAO); the close similarity of the performances of some hydrocracked oils and PAO, and their significantly lower cost, make them increasingly attractive for lubricant formulations.

Figure 64 illustrates the development of VHVI and UHVI oils (HC-II and HC-III oils) in Europe, Asia, and North America. Whereas Shell and BP in France and Union Fuchs in Germany were the only manufacturers of VHVI oil in the 1980s, by the mid-1990s similar activities had spread from Western Europe around the world [66].

16.2. Laboratory Methods for Testing Lubricants

The properties of lubricants are mostly determined by standardized test methods.

The most common laboratory test methods are listed in the following sections and an overview of the corresponding international standards is given e.g., AFNOR [529], ASTM [530], DIN [531], IP [532], and ISO [533].

16.2.1. Density

For the determination of density of lubricants different test equipment is in use such as hydrometer, pycnometer, hydrostatic balance or digital densimeter.

Table 51. Typical data for 4 mm^2/s base oils (HC oils) in comparison with conventional solvent refined oils and polyalphaolefins

	Solvent refined	HC-1	HC-2	HC-3	Polyalphaolefins
Viscosity, mm^2/s at 100 °C	4	4	4	4	4
Viscosity index	100	105	125	130	125
Volatility, Noack evaporation loss, wt %	23	18	14	13	12
Pour point, °C	−15	−15	−18	−20	−65
API group	I	II	III		IV

Table 52. Typical hydrocarbon composition of HC oils in comparison with conventional (4 mm^2/s) solvent refined oils and polyalphaolefins

	Solvent refined SN 100	HC-1	HC-2	HC-3	Polyalphaolefins
n- and Isoparaffins, %	25	30	55	75	96
Monocycloparaffins, %	20	35	24	15	4
Polycycloparaffins, %	30	34	20	10	–
Aromatics, %	24	0.5	0.3	0.1	–
Thiophenes, %	0.5	–	–	–	–

Figure 64. Development of VHVI and UHVI oils (HC-II and HC-III) in Europe, Asia and Northern America

16.2.2. Viscosity

For the determination of viscosity capillary viscometers, falling ball and rotary viscometers are used.

Capillary viscometers (DIN 51562/ASTM D 445) are generally used for most of the automotive and industrial lubricants for determination of the kinematic viscosity. The most frequently used viscometers are Ubbelohde for transparent liquids, and Cannon – Fenske viscometers (DIN 51366).

Rotary viscometers use the torque on a rotating shaft to measure a fluid's resistance to flow. The shear rates can be changed by modifying the speed of rotation, rotor dimensions and the gaps between rotor and stator.

The CCS apparent viscosity is measured in a range between 2.000 and 20 000 mPa · s at temperatures between −5 and −30 °C (ASTM D 2602/DIN 51377). The CCS apparent viscosity correlates excellently with low temperature engine cranking.

The MRV (ASTM D 3829) is applied to measure the borderline pumping temperature and is

related to the mechanism of pumpability of engine oils.

The Brookfield viscometer (ASTM D 2983/DIN 51398) is used for the determination of the low shear rate viscosity of automotive fluid lubricants in a temperature range between −5 °C to +40 °C.

The Ravenfield viscometer (ASTM D 4741) allows the determination of dynamic viscosity of engine oils at 150 °C using a high shear rate tapered/plaque viscometer.

16.2.3. Refractive Index

The refractive index (DIN 51423/ASTM D 1218) is used for the characterization of the structure of petroleum hydrocarbons like the density. Furthermore, it is mostly used as a property for fast identification of a product.

16.2.4. Structural Analyses

The amount (%) of aromatic and paraffinic hydrocarbons in a mineral oil can be determined by the carbon distribution method developed by Brandes [534]. The method determines the infrared absorbency at wavelengths of 1620 and 724 cm^{-1}, which correspond to the stretching frequencies of the aromatic and paraffinic hydrocarbons respectively. However, this method gives no information on isoparaffins and does not take into consideration sulfur content.

According to DIN 51378/ASTM D 2140 the kinematic viscosity at 40 °C, the density at 20 °C and the refractive index as well as the sulfur content are determined. From these characteristics the percentage of aromatic, naphthenic and paraffinic hydrocarbons is determined with or without sulfur correction.

For improved characterization chromatographic, gas chromatographic and NMR spectroscopy methods as well as element analyses of the narrow distillate fractions have to be carried out.

16.2.5. Flash Point

For the determination of the flash point closed and open cups are used. The open cup flash point is described according to DIN ISO 2592/ASTM D 92. The closed cup method is mainly used for lubricants with a flash point > 79 °C.

For lubricants and mixtures with solvents the flash point is determined by closed cup methods according to Abel – Pensky (DIN 51755) or Pensky – Martens (DIN 51758/ASTM D 93).

16.2.6. Surface Phenomena

During storage or application lubricants are in a continuous contact with air or even with water, which might lead to formation of foam or emulsion. For evaluation of the behavior of base oils and lubricants the following methods are applied.

Air Release. For the determination of air release behavior (DIN 51381/ASTM D 3427) compressed air is blown through the test oil which is heated to a defined temperature. After the airflow is stopped the time required for the air entrained in the oil to be released is determined. This is the time at which the density is narrowed to 0.002 g/mL of the density of the pure oil.

Demulsibility. For the determination of demulsibility (DIN ISO 6614, ASTM D 1401) 40 mL lubricant and 40 mL of distilled water are stirred at a defined temperature in a graduated cylinder. After stirring the time required for the separation of oil from the water is determined. If after 30 min standing the separation is not totally completed the volume of oil, water and emulsion is reported.

Foaming Characteristics. The foaming characteristics (ASTM D 892) are determined by blowing for 5 min a constant rate of air through the oil. The volume of the foam is measured immediately and after settling for 10 min.

16.2.7. Cloud Point, Pour Point

The pour point (ASTM D 97) is the lowest temperature expressed as a multiple of 3 °C at which the test fluid is observed to flow when it is cooled and examined under defined conditions.

The cloud point (ASTM D 2500) is the low temperature behavior where an oil starts to become cloudy when it is cooled under defined conditions.

16.2.8. Aniline Point

The aniline point (DIN 51775/ASTM D 611) is the temperature at which equal volumes of hydrocarbon oils and aniline separate in two phases. This value gives an indication on the structure of mineral oils. The higher the temperature of separation the more paraffinic is the oil.

16.2.9. Water Content

For water contents $\geq 0.05\,\%$ ASTM D 95 is used. This test procedure involves azeotropic reflux distillation of the oil with xylene with water separating from the reflux distillate.

For lower water contents between 50 and 1000 ppm the Karl Fischer method (DIN 51777/1/ASTM D 1744) is more accurate.

16.2.10. Ash Content

For unused oils the determination of the ash content (DIN EN 7/ASTM D 482) gives an indication of purity.

The content of acid constituents is characterized by the determination of sulfated ash from unused lubricating oils containing additives. Those additive concentrates contain a variety of metals. As this is a time consuming method it has more or less been replaced by determination of elements by atomic absorption, X-ray fluorescence or emission spectroscopy.

16.2.11. Acidity, Alkalinity

The neutralization number of base oils is determined by titration against a color indicator (ASTM D 974). When the oil contains additives such as dispersants or detergents, the end point of titration is difficult to observe, potentiometric titration is used.

Another method is the total acid number (TAN/ASTM D 664). The acidity of unused oils and fluids is normally derived from the type and concentration of specific additive material whereas the acidity of used oil is of interest to measure the degree of oxidation of the fluid.

The TBN characterizes the alkaline reserve. It is particularly used for engine oils where by acidic combustion products use up the alkaline reserve.

16.2.12. Aging Tests

Aging tests are carried out on base oils as well as fully formulated products to test the efficiency of additives. The different oxidation stability tests are the most common ways for testing the aging properties of lubricants. There is a big variety of standardized test methods. The majority of these tests is based on exposing the test fluids to oxygen or air at relatively high temperatures in presence of catalytic metals to increase oxidation rates and to reduce the testing period.

The turbine oxidation stability test (TOST) is used to evaluate the oxidation stability of inhibited steam turbine oils in presence of oxygen, water, copper and iron catalyst at 95 °C. The test is continued until the TAN measured reaches at least 2.0 mg KOH/g. The number of test hours required for the oil to reach 2.0 mg KOH/g is the 'oxidation lifetime' of an oil.

The oxidation stability by rotary bomb test (ASTM D 2272) oxidizes the oil at 150 °C in presence of water, metallic copper catalyst and oxygen at 620 kPa pressure. The time is registered to reach a specific pressure drop and this is an indication of the oxidation stability.

The aging test according to Baader (DIN 51554) is an oxidation test at atmospheric air and intermittent immersion of a copper spiral at a test temperature of 95 °C. After a given time the saponification number in mg KOH/g is measured.

In the oxygen bomb method a lubricating grease is oxidized in a bomb heated to 99 °C and filled with oxygen at 758 kPa overpressure. After a defined time the pressure drop is recorded. The degree of oxidation after a given period of time is determined by the corresponding decrease of oxygen pressure.

16.2.13. Hydrolytic Stability

The hydrolytic stability of additives is commonly tested in the beverage bottle method (ASTM D 2619). The method differentiates the relative stability of fluids in the presence of water under the conditions of this test.

16.2.14. Corrosion Tests

The detection of copper corrosion (ASTM D 130/DIN 51759, Part 1) describes a simple procedure for investigating the aggressiveness of the fluid towards a polished copper strip at a temperature for a time selected for the fluid under test.

The rust preventing characteristics of inhibited mineral oils (ASTM D 665/DIN 51585) in the presence of water is used for evaluating corrosion preventive properties of steam turbine oils and hydraulic oils.

For the evaluation of rust preventive properties of metal corrosion inhibitors under high humidity (ASTM D 1748/DIN 51359), steel panels are prepared to a prescribed service finish and dipped in a test oil.

16.2.15. Oil Compatibility of Seals and Insulating Materials

An essential requirement for lubricants is that they should be compatible with seal materials as they are frequently in prolonged contact at elevated temperatures. In all the test methods applied, well defined test specimens are immersed in the lubricant for a defined time at defined temperatures. After the test period the volume change, weight loss, and change of mechanical properties are evaluated.

16.2.16. Evaporation Loss

The volatility of oils is determined by evaporation loss expressed as a percentage by mass of nonadditive and additive-type lubricating oils (ASTM D 5800/DIN 51581, Part 1). The procedure according to Noack has been developed for motor oils but it can also be applied to other lubricants. A well defined air stream is directed over the oil which is heated for 1 h to 250 °C. The evaporation loss is established by weighting.

16.2.17. Analysis of Grease

The consistency of lubricating greases is measured by penetration of a standard cone (ASTM D 217/ISO 2137). Penetration is the depth in tenths of millimeters where a standard cone assembly sinks into the grease.

The dropping point of lubricating greases (ASTM D 566/ISO 2176) is the point at which a conventional soap-thickened grease passes from semisolid to a liquid state under the conditions of the test or the temperature at which a non soap-thickened grease rapidly separates oil.

16.3. Mechanical – Dynamic Testing Methods for Lubricants

Mechanical – dynamic lubricant testing has become an essential element in the development of modern lubricants. In this respect, standardized tribological, mechanical – dynamic testers and test methods play a decisive role in the development of lubricants. A variety of so-called house-internal methods complete the range of today's tribological, mechanical – dynamic tests.

16.3.1. Tribological System Categories within Lubricant Tests

Today's wide range of tribological, mechanical – dynamic testers and testing methods includes small laboratory instruments and field tests under real conditions. The various types of lubricant test are classified, for example, by the German DIN 50322 [535].

16.3.2. Standardized and Nonstandardized Test Methods for Lubricants

The most important test methods, used worldwide by many laboratories, are, above all, the ISO, CEC, ASTM, IP and DIN standards. Often, these standardized test methods will include overlapping among the procedures or even technically equivalent methods.

The common laboratory testers used in today's lubricant development and the tests performed with these testers [536, 536, 537], are listed in Table 53.

Table 53. Common laboratory testers and test standards.

Tester	Application	Test method
Roll stability test apparatus	standard test method for roll stability of lubricating grease	ASTM D 1831-94
SKF (EMCOR) Anti-rust rig	determination of rust prevention characteristics of lubricating greases	IP 220/93 DIN 51802
Water-washout apparatus	standard test method for determining the water washout characteristics of lubricating grease	ASTM D 1264-93 IP 215/93 DIN 51807 Part 2
ASTM Torque test apparatus	standard test method for low-temperature torque of ball bearing grease	ASTM D 1478-91
IP Low temperature torque apparatus	determination of low-temperature torque of lubricating grease	IP 186/93
ASTM Leakage testing apparatus	standard test method for leakage tendencies of automotive wheel bearing greases	ASTM D 1263-94
FAG Noise testing apparatus	noise inspection of lubricating greases (computer-aided)	FAG-QV3.102FB MGG 11
SKF Noise testing apparatus	noise inspection of lubricating greases (computer-aided)	SKF specification MVH 90 B
Sonic probe type apparatus	standard test method for sonic shear stability of polymer-containing oils	ASTM D 2603-91
Shell delimon rheometer	standard test method for determining the delivery resistance using the shell delimon rheometer	E-DIN 51816, part 1
Evaporation loss tester	standard test method for engine and hydraulic oils for the determination of the evaporation loss and sediments	WOLF specification
Incline tribometer	standard test method for determining friction coefficients	H. Schmidt Specification

16.3.3. Common Mechanical – Dynamic Testers

Four-Ball Apparatus. The four-ball apparatus is one of the oldest and best-known model test benches for liquid and solid lubricants. Because it furnishes very precise lubricant key values, it is used all over the world. In this apparatus, a roller-bearing ball rotates under pressure and at a constant speed on three fixed steel balls of the same type in an oil bath or lubricated with a solid lubricant (Fig. 65). The gradual increase in pressure enables the determination of weld loads, supplies key values concerning loadability, or enables allows the determination of the friction or start-up behavior in relation to the lubricant. In addition, the application of relatively small loads over a longer period of time enables the determination of key wear protection values and the friction values of lubricants. During these tests, the surface of the ball surface will produce wear impressions which when measured will lead to information on the effects of additives.

In the late 1990s several adapters have been developed for the four-ball apparatus to furnish information on the pitting load capacity and the shear stability of polymer-containing lubricants. Further modifications of the adapter testers enable the determination of friction torque and temperature in the immediate proximity of the outer ring of the roller bearings.

Figure 65. Diagram of the test using the four-ball, apparatus

As ever, today's numerous specifications for gear and hydraulic lubrication and for all types

of greases and pastes contain key values for the minimum requirements for lubricants.

Reichert Friction Wear Tester. The Reichert friction wear tester (Fig. 67) plays an important role in the determination of the wear rates of water-containing and non water-containing coolant lubricants.

Figure 66. Reichert friction wear tester

By means of a double lever handle system, a firmly clamped cylindrical roll is pressed, under load, against a slip ring rotating cross-directionally to the test roll. Approximately the lower third of the test ring is dipped into the test fluid. After a walkway of 100 m at a constant rotational speed of the rotating slip ring, the elliptical wear mark produced on the test roll is measured.

Falex Tester. The Falex tester (Fig. 66) is used for testing lubrication oils and greases. It is used worldwide to determine the friction, load stage, and wear key values of a lubricant.

Figure 67. Falex teste

A soft steel shaft, either greased or in an oil bath, rotates under pressure between two hardened steel prisms. At constant rotational speed the test load is increased in three steps. If a lubricant withstands the applied load, the wear-loss of the softer shaft is measured.

Timken Tester. The Timken tester (Fig. 68) is particularly suitable for determination of the key values of greases, lubrication oils, and solid lubricants such as pastes. The apparatus tests the load stage and the wear behavior of the lubricants under mixed-lubrication conditions.

In the metallurgical and steel industry the Timken tester is still particularly important all over the world.

The lubricant test is conducted in a friction system comprising a cuboid block and a test ring. The tester is run with a lubrication oil circulation system, which can be adjusted variably, and a grease feeder with a feed volume of 45 g/min. The test force, which is gradually increased, is brought into the friction system via the test block. Individual weighing of the test block and the test enables determination of the wear loss in a load stage. The test period for each load stage is 10 min at a rotational speed of 800 min^{-1}.

Translatory Oscillation Apparatus (SRV). The translatory oscillation apparatus (Fig. 69) is used to test lubrication oils, grease, and solid lubricants. It is used worldwide to record the friction value, wear behavior, and load stage of a lubricant in key figures. The lubricant test is conducted under mixed-lubrication conditions.

Figure 68. Timken tester

This, in particular, enables the testing of wear-protective and scuffing-preventing additive systems which are part of EP and AW active substances.

Test pieces made of roller bearing steel are inserted in the test chamber of the oscillation apparatus and wetted with the lubricant to be tested.

A great advantage of the tester is the possibility of performing systematic studies simply and quickly, with only small quantities of lubricant. These variations of testing conditions, which vary from the test standards, do, however, require sufficient experience with this tester and the interpretation of its results.

FZG Gear Test Rig. The FZG gear test rig (Fig. 70) is a so-called component test rig with a direct relationship to the machine or transmission system. The FZG gear test rig is one of the most important tribological test benches for gear lubrication and hydraulic oils worldwide. It is predominantly used to determine the maximum load of lubricants for all types of gear drive.

The test bench consists of a bed plate (a) with two firmly mounted gears which are coupled to each other through shafts. During operation the flanges of the load clutch (b) are connected with each other by means of screws. If these screws are loosened and one load clutch flange is locked using the lock pin (c), the second load clutch flange can be twisted by a lever arm with weight pieces, thus initializing a torque in the test bench. If the two flanges of the load clutch are rescrewed to each other and the load lever is removed, the initialized torque in the shafts is sustained. Accordingly, the forces also strain the toothing in the test and drive gears.

The FZG gear test is used for the load stage test (FZG test method A/8.3/90), micropitting test (GF-C/9(10)/8.3/90), pitting load capacity test (P-C/9(10)/8.3/90), wear load capacity test (ASTM D 4998 – 95), and gear efficiency test (VW-PV 1454).

FAG FE9 Roller Bearing Grease Tester. The FAG FE9 roller bearing grease tester (Fig. 71) has been developed for component tests for greases under realistic conditions. The service life of the grease is determined from the operating temperature, the load, and the rotational speed of the test bearing.

Test method A/1500/6000 has been standardized according to DIN 51821, part 2. The angular contact ball-bearing in the tester is filled with approximately 2 mL grease. The test-bearing is loaded with an axially aligned test force of 1500 N at a rotational speed of 6000 min^{-1}. The test temperature can be selected from within the range 120 – 200 °C (maximum) and is applied to the test bearings by means of heating elements. The high test temperatures in the greased test bearing facilitate oxidation of the lubricants. Failure of a lubricant in the test bearing results in a clear increase of the bearing friction.

FAG FE8 Roller Bearing Grease Tester. The FAG FE8 roller bearing grease tester (Fig. 72) is one of the most versatile component testers for lubricants. It tests the suitability of lubricants and lubrication oils with regard to the friction and long-term wear protection behavior

Figure 69. Diagram of the linear oscillation tester (SRV) and possible test sample geometries

Figure 70. Diagram of the FZG gear test rig

of the lubricants in roller bearings for almost all applications.

Two test bearings of the test head of the FE8 are rigged, axially using disk springs, back to back. The test bearings are lubricated with grease or, by means of a circulation lubrication system, oil. The drive of the test bearings is effected through the inner races of the test bearing on the drive shaft. The test bearing's outer races are fixed in the test head box. By means of a wire rope the test head is fixed to a load cell which records the dynamic friction torque during the test run. An outer radiant heater, placed on the test head as a heating cap, enables tests at bearing temperatures up to 200 °C.

The bearing load is equivalent to 10, 20, 50, or 80 kN. The engine speed can be varied from 7.5 to 3000 min^{-1}.

Synchronizer Rig SSP 180. The synchronizer rig SSP 180 is a component tester developed to test the different types of synchronizer system normally used in the automotive industry and found in all kinds of manual transmission.

The durability to be determined depends not only on the synchronizer component system used but above all on the lubricant used. Nowadays numerous lubricants are perfectly suitable for use in one tribological system but cannot be used in another. Thus, this component test and this relatively new tester play an important role

Figure 71. Test bench of the FAG-FE9 roller bearing grease tester. A) Open tester bearers; B) Covered tester bearings without grease reservoir; C) Covered tester bearings with grease reservoir

Figure 72. Test bench diagram of the FAG FE8 roller bearing grease tester

in the development and pre-selection or screening of new lubricants and additives for manual transmissions.

Diesel Injection Nozzle. This tester is, on the one hand, used in laboratories to test liquid lubricants and, on the other, enables a lubricant test with an aggregate. This test method has been developed to determine the change in viscosity of polymer-containing hydraulic and engine oils for in relation to the temperature.

For a specified number of run-through cycles, a sample (170 mL) of lubricant is subject to a shear stability test in the tester, which consists mainly of a two-cylinder pump and an injection nozzle set for calibration oil shear stability. Before and after the shear stress the kinematic viscosity is determined at 40 °C with hydraulic oils or 100 °C with engine oils.

17. Economic Aspects

In 1999, 37.3×10^6 t of lubricants were consumed worldwide (56 % automotive lubricants, 29 % industrial lubricants, 5 % marine oils, 10 % process oils). Of total industrial oils, 38 % were hydraulic oils, 7 % industrial gear oils, 33 % other industrial oils, 17 % metalworking fluids (including temporary corrosion preventives whose multipurpose function often includes lubrication) and 5 % greases.

Table 54 shows the 1999 per capita consumption for various regions. North America and Western Europe make up 40.6 % of world lubricant consumption even though these regions only account for 10.7 % of the world's population [538].

Table 54. 1999 Per capita consumption of lubricants (kg/a)

North America	31.5
Australia/Oceania	17.4
Western Europe	15.3
Central/Eastern Europe	11.9
Latin America	5.8
Asia	3.2
Africa	2.2
World	6.1

Since 1975, quantitative lubricant demand has significantly detached itself from gross national product and also from the number of registered vehicles. This quantitative view gives an inadequate impression of the significance of the lubricants business today. In almost all areas, products now have a longer life and offer greater performance, i.e., specific lubricant consumption has declined but specific revenues have increased noticeably. This is also confirmed by the volumetrically very important group of engine oils: the doubling of requirements with extended oil change intervals in recent years have quadrupled the cost of such oils.

As about 50 % of the lubricants sold worldwide end in and thus pollute the environment, every effort is made to minimize spillages and evaporation. An example is diesel engine particulate emissions, about a third of which are caused by engine oil evaporation.

A further incentive to reduce specific consumption is the ever-increasing cost of disposal or recycling of used lubricants. But this again creates new demands on lubricants because reduced leakage losses means less topping-up and less refreshing of the used oil. The new oils must therefore display good aging stability.

Bearing in mind the growth potential in Asia where per capita consumption of lubricants in some areas is extremely low (1999: India 1.1 kg, China 2.5 kg) and a continuing reduction in volumes or stagnation in Western industrialized countries, overall global growth is forecast. This has been estimated to be 6.5 % between 1997 and 2002 [539].

Worldwide, there are 1700 lubricant manufacturers ranging from large to small. On one hand there are vertically-integrated petroleum companies whose main business objective is the discovery, extraction and refining of crude oil. Lubricants account for only a very small part of their oil business. At present, there are about 200 such national and multinational oil companies engaged in manufacturing lubricants. In contrast, the 1500 independent lubricant companies view lubricants as their core business. While the large, integrated companies focus on high-volume lubricants such as engine, gear and hydraulic oils, many independent lube companies concentrate on specialties and niche business.

Less than 2 % of lubricant manufacturers produce more than 60 % of global lubricant volumes. Tables 55 and 56 show the world's largest manufacturers of lubricants and industrial lubricants.

Table 55. World's largest lubricant manufacturers (2000)

	Company	Country
1	Exxon Mobil	USA
2	Shell	UK / Netherlands
3	Chevron Texaco Caltex	USA
4	BP CASTROL	UK
5	SINOPEC / CNPC	China
6	Pennzoil Quaker State	USA
7	Total Fina Elf	France
8	Nippon Mitsubishi Oil / Fuji Kosan / Koa Oil	Japan
9	Lukoil	Russia
10	Valvoline	USA
11	SUN	USA
12	IDEMITSU	Japan
13	Fuchs	Germany
14	Indian Oil	India
15	AGIP / Petrogal	Italy
16	Repsol – YPF	Spain

Table 56. World's largest manufacturers of industrial lubricants (2000)

	Company	Country
1	Exxon Mobil	USA
2	Shell	UK / Netherlands
3	Sinopec / CNPC	China
4	Chevron Texaco Caltex	USA
5	BP Castrol	Germany

The independent lubricant manufacturers rarely operate base oil refineries. They buy their raw materials from the chemical and oleochemical industry and their mineral base oils from the large petroleum companies.

The production of simple lubricants normally involves blending processes but specialties often require the use of chemical processes such as saponification (in the case of greases), esterification (when manufacturing ester base oils or additives) or amidation (when manufacturing components for metalworking lubricants). Further manufacturing processes include drying, filtration, homogenizing, dispersion or distillation.

Towards the end of the 1990s, the petroleum industry was affected by a wave of mergers which will continue. These created new and larger lubricant structures at the merged companies. The principal reasons for these mergers were economic factors in crude oil extraction and refining which resulted in lower refining margins.

Grease Market. In 1995 37.1×10^6 t of lubricants were used worldwide. Of these 1.2×10^6 t were greases [541]. The NLGI has reported that 710 830 t of grease were produced in 1999 [542] and it must be considered that only ca 60 % of the worlds grease manufacturers contributed to this figure.

Conventional lithium greases (52.8 %) are the most used. Lithium complex greases account for 14.1 % and are followed by conventional calcium greases with 9.7 % (Table 57).

Table 57. Global share of thickeners (1999)

Thickener system	%
Conventional lithium soap	52.8
Lithium complex soap	14.1
Conventional calcium soap	9.7
Aluminum complex soap	4.7
Polyurea	4.3
Organophilic clay thickeners	3.5
Calcium complex soap	3.2
Sodium soap	2.5
Anhydrous calcium soap	2.0
Other metallic soap	1.2
Other thickeners	2.0

Although lithium soap based greases are the most used products worldwide, there are significant differences among local markets with regard to other grades of grease. In the US and Canadian market lithium complex greases (29.6 %) are the most used. Aluminum complex greases (6.8 %) are also above the global average. In Europe the calcium complex greases (9.4 %) are ahead of lithium complex grades (8 %). In Japan the polyurea greases (14.6 %) are behind conventional lithium greases (58.2 %); both figures are above the global figures (Table 58).

Table 58. Local share (%) of high-temperature thickeners (1999)

Thickeners	Global	USA	Europe	Japan
Lithium complex	14.1	29.6	8.6	0.2
Aluminum complex	4.7	8.0	4.7	2.7
Polyurea	4.3	7.6	1.7	14.5
Organophilic clay	3.5	6.4	2.2	0.5
Calcium complex	3.2	2.2	6.6	0.3

The main consumer market is the automotive market, with ca 50 %. The grease used are conventional lithium greases, conventional calcium greases, and often sodium greases for relubrication of trucks, construction, farming, and forestry equipment, and old-fashioned cars.

The industrial grease market is divided into a wide range of different and tailor-made greases. Big consumers are steel mills, mines, especially open-pit mines, railroad companies, motor companies, and manufacturers of all kind of machinery; they rely on many suppliers. Often these suppliers emphasize the performance of a wide variety of greases. Among industrial grease customers the roller bearing industry is very important; in addition to high-quality conventional lithium greases they increasingly need specific greases to fulfil their customers' requirements.

In Germany products used in switches have been completely replaced by ester based biodegradable greases. Trials with biodegradable wheel-flange greases in Austria, The Netherlands, and Germany [543] have been successfully completed. Testing in Canada of a biodegradable grease for rail track-side lubrication proved its superior load-carrying and wear-protection performance [544].

18. Disposal of Used Lubricating Oils

Figure 73 shows the fate of lubricants sold every year in Western Europe. Only 49 % are collectable and only 28 % are actually collected [545]. (The chart also includes process oils which are not lubricants.) To ameliorate this situation, the following objectives should be achieved: the intensive gathering of collectable oils and an improvement in the environmental compatibility of the lubricants.

18.1. Possible Uses of Waste Oil

Used lubricants represent a problem for the environment. Their ecologically-compatible use is therefore an important environmental protection measure.

The demand that new lubricants should be made of used products is based on the erroneous notion that re-refining can restore the original condition of a lubricant. In fact, lubricants lose value during use and re-refining, at best, can only restore the value of base oils. In the case of conventional mineral oils, this value is only slightly higher than that of fuels or heating oils. This is also the reason why re-refining is hardly economical without legislative provisions or subsidies. From a global competition point of view, other disposal options include the direct incineration of untreated waste oils, the simple pretreatment (cleaning) and alternative uses such as flux oils for bitumen or for the manufacture of secondary feeds for catalytic crackers and as blending stock for high-sulfur fuels.

18.2. Legislative Influences on Waste Oil Collection and Reconditioning

The EC Directive 87/101 contains a recommendation to all member countries concerning the regeneration of used oils insofar as economic, technical and organizational conditions allow. Emission thresholds for incineration plants (< 3 MW) make the burning of untreated used oils difficult. However, in some European countries, incineration in smaller incineration plants is still possible. Legislation permits incineration in high-temperature furnaces and by the cement manufacturing industry. In some countries, fuels and heating oils reclaimed from used lubricants are not taxed and are thus subsidized.

The polychlorinated biphenyl (PCB) problem which surfaced in Europe in 1983 significantly influenced European legislation on wastes, i.e., two categories of waste oil were created: Used oils which contain more than 0.2 % chlorine cannot be re-refined and are subject to expensive disposal procedures. This in turn has promoted the development of chlorine-free lubricants.

Re-refined used oils are subsidized in Italy. In Germany, the manufacturers of lubricants (including distributors) have transferred their legal requirement to properly dispose of waste oils to collection organizations. In 1999, these received about 90 per tonne from the lubricant consumers.

In the USA, state law on this subject differs. Since 1986, used oils have been classified as hazardous wastes in California and other states have since followed. In some states, the collector is

Figure 73. Lubricating oil supply, use and disposal in Western Europe (CONCAWE 1996) [545]

paid up to 20 cents per gallon by the oil user, in other states the collector has to pay.

Viewed globally, some extremely differing situations exist. While some countries do not regulate the collection and disposal of used oil and used oil is generally not collected, other countries can point to high collection and disposal rates (in 1996, 99 % of used oils were collected or properly incinerated in Germany; but only 60 % in the USA).

18.3. Re-refining

The re-refining of used oils to lube base oils started in 1935 [546]. The principal reasons why re-refining was unable to find acceptance were: high process costs and therefore high selling prices compared to relatively low virgin oil prices, inadequate removal of carcinogenic polycyclic aromatics, the negative image of such oils in most markets and the increasing complexity of base oil blends in engine and other lubricants. In Western Europe, only 7 % of base oil demand was satisfied by re-refined products in 1998.

Numerous re-refining technologies have been developed over the last 20 years. Many were patented but only few were suitable for large-scale application [547–552].

In general, the process stages, given below, are common to all the different methods.

1) Separation of larger solid impurities along with most of the water. This is normally achieved by sedimentation.
2) Separation of the volatile parts (fuel residues in engine oils, solvents and low boiling-point lubricant components), normally atmospheric distillation. The separated light hydrocarbons can usually be used in-house for energy generation.
3) Separation of the additives and aging by-products. This can occur by acid refining, solvent (propane) extraction, vacuum distillation or partly also by hydrogenation.

4) Finishing process to separate any remaining additives, aging byproducts and refining reaction products. This is normally done by hydrofinishing, with absorbents such as bleaching clay or mild, selective solvent extraction (e.g., furfural).

Sulfuric Acid Refining (Meinken). The sulfuric acid refining process was mostly developed by Meinken. Compared to older acid-based methods, various process stages reduce the amount of acidic sludge and used bleaching clay generated as well as increasing the lube oil yield.

Due to the acidic sludge problem, acid refining has largely been replaced by other methods. However, numerous such plants were still in operation in 1999. Figure 74 shows the flow sheet of a Meinken plant.

Propane Extraction Process (IFP, Snamprogetti). Of the principal extractive refining processes, the IFP (Institut Français du Pétrole) technology is worth mentioning. This process initially used propane extraction together with acid refining and later together with hydrofinishing. Propane extraction is also used by Snamprogetti (Italy) as the main refining step before and after vacuum distillation. Figure 75 shows the process with propane extraction [553], [554].

Mohawk Technology (CEP – Mohawk). The Mohawk Process (subsequently CEP – Mohawk) using high pressure hydrogenating was introduced in the USA at the end of the 1980s. The process begins with thin-film vacuum distillation of the waste oil (after flashing the light hydrocarbons and water). This is followed by hydrogenation of the distillate at 6900 kPa over a standard catalyst. Special steps realized catalyst life of 8 to 12 months, which was essential for the economy of the process.

A marked reduction in the amount of water which must be treated as effluent as well as the cheaper materials for construction (absence of corrosion) are further advantages. The Mohawk process which is based on the KTI process has been licensed for Evergreen Oil (USA and Canada).

KTI Process. The KTI (Kinetics Technology International) process combines vacuum distillation and hydrofinishing to remove most of the contamination and additives. The key to the process is the thin-film vacuum distillation to minimize thermal stress through mild temperatures not exceeding 250 °C.

The hydrofinisher removes sulfur, nitrogen and oxygen. The yield of finished base oils is high (82 % on a dry waste oil basis). Figure 76 shows the flow chart of this process.

PROP Process (Fig. 77). The PROP technology was developed by Phillips Petroleum Company. The key elements of the process are the chemical demetallization (mixing an aqueous solution of diammonium phosphate with heated base oils) and a hydrogenation process. A bed of clay is used to adsorb the remaining traces of contaminants to avoid poisoning of the Ni/Mo catalyst.

Safety Kleen Process. The Safety Kleen process uses atmospheric flashing for removing water and solvents, a vacuum fuel stripper, vacuum distillation with two thin-film evaporators, and a hydrotreater with fixed bed Ni/Mo catalysts. When using high severity the hydrotreater can reduce the content of polynuclear aromatics; it also removes higher boiling chlorinated paraffins.

Figure 78 shows a simplified block diagram. In 1998 the Safety Kleen process was used in the largest waste oil re-refinery in the world (East Chicago, Indiana, USA, plant capacity 250 000 t/a).

DEA Technology (Fig. 79). The best results with regard to the technical and environmental quality of the re-refined oil and the elimination of PAH are provided by a combination of thin film distillation followed by selective solvent extraction. In this process, the distillate from vacuum thin-film distillation towers equipment at the re-refinery (Dollbergen/Germany) are finally treated in a lube refinery solvent extraction plant followed by hydrofinishing (DEA, Hamburg/Germany). After this extraction process, the PAH content is lower than that of virgin solvent neutrals [554].

Other Re-refining Technologies. *Vaxon* (Enpotec fabrication facilities in Denmark)

Figure 76. Flow chart of the KTI Process: thin film evaporator (TFE) with hydrotreatment

Figure 77. Flow chart of the PROP Process

Figure 78. Safety Kleen process

Figure 79. Introduction of selective solvent extraction in the re-refining process (DEA / Mineralöl-Raffinierie Dollbergen, Germany)

uses three or four vacuum cyclone evaporators and finishing treatment with chemicals for re-refining of lubricating oils.

The key step in the *ENTRA technology* is the special vacuum evaporation in a vacuum linear tubular reactor (single tube). After continuous evaporation by means of rapidly increasing temperature, vapor condensation is performed by fractional condensation. Complete dechlorination can be achieved with metallic sodium. Clay polishing is used as a finishing process.

The *thermal deasphalting* (TDA) process has been developed by Agip Petroli/Viscolube using the technology of PIQSA Ulibarri in Spain. The process is based on chemical treatment to facilitate subsequent deasphalting.

The deasphalting process is combined with high fractionating efficiency (TDA unit). Finishing can be performed by clay treatment or hydrofinishing.

19. Toxicology and Occupational Health

19.1. Safety Aspects of Handling Lubricants (Working Materials)

Lubricants are working materials when personnel contact with these substances via contact with the skin or clothes or by inhalation or swallowing. Toxicological, medical and industrial hygiene aspects thus have to be considered.

19.1.1. Polycyclic Aromatic Hydrocarbons (PAK, PAH, PCA)

The largest proportion of raw materials in metalworking lubricants are high boiling point petroleum cuts which contain very few polycyclic hydrocarbons (PAH).

Neat metalworking oils are in the forefront of the PAH discussion because these can directly contact a comparatively large number of people via the inhalation of oil mists. Efforts were already made in the past to evaluate the cancer risks posed by neat cutting oils by determining their concentration of polycyclic aromatic hydrocarbons.

19.1.2. Nitrosamines in Cutting Fluids

Discussions on this subject were triggered by the use of alkali metal nitrites as corrosion inhibitors. The most prominent was and is sodium nitrite, a widely available and cheap substance with good inhibitor properties. Reaction of secondary amines with nitrites can lead to the formation of nitrosamines, 80 % of which are carcinogenic. Sodium nitrite can be found, above all, in low-mineral oil (semisynthetic) or hydrocarbon-free (fully synthetic) solutions. These concentrations are so high that water-miscible application concentrations of 0.05 to 0.2 % can be found. If other, mostly organic inhibitors are used, significantly lower concentrations can be used. Apart from the use of sodium nitrite in water-miscible cutting fluid concentrates, it can also be directly added to water-miscible cutting fluids by consumers.

While the carcinogenic effect of some nitrosamines has been known since the mid-1950s, it was assumed that the reaction between nitrite and amines could not take place in cutting fluids because these were alkaline and the reaction requires an acidic environment. However, if cutting fluid mists are swallowed, nitrosamines can be formed in the acid milieu of the stomach.

High-performance liquid chromatography and other analytical methods were used to prove the presence of between 0.02 and 2.99 % of diethanol nitrosamine in cutting fluid concentrates of fully synthetic products. The pH of the products was between 9 and 11.

The nitrosamine discussions have led a number of cutting fluid manufacturers to develop nitrite-free cutting fluids. However, it must be remembered that in the past, a much larger proportion of water-miscible cutting fluids were free of nitrite.

19.2. Skin Problems Caused by Lubricants

In the metalworking industry, a large proportion of the problems are caused by contact with lubricants. Chip-forming machining operations with water-miscible and neat cutting oils are in the forefront because of the large number of contact possibilities.

Oil acne (particle acne) is one of the most common skin problems caused by contact with neat cutting and grinding oils. Usually it is not the oil itself but small particles such as metal fragments which are the cause. This is why this problem is often referred to as particle acne. Oil acne can appear wherever oil directly contacts the skin and this can include oil-stained clothing. Body areas particularly at risk are the lower and upper arms, the backs of hands, the face, thighs and waist.

Improvements in machine tools such as machine encapsulation, fume extraction, the avoidance of oil mists and general automation means that personnel have less contact with oil and the cases of oil acne have fallen significantly in recent years. The frequency of oil acne cases in factories is a measure of the hygiene standards in force and the personal cleanliness of machine room personnel.

Oil Eczema. The term ‘oil eczema’ encompasses several skin problems. These look like scaly or wet reddened areas, sometimes with a cracked surface.

Acute toxic eczema is caused by the direct effect of the substance on the skin and causes a particular appearance.

Degenerative eczema is the most important skin problem caused by water-miscible cutting fluids. Long-term contact between the cutting fluid and the skin produces signs of degeneration and a breakdown of the skin’s defenses. Key factors are the alkalinity of the fluid, the long-term wetness and specific product ingredients and particularly boundary-active substances from emulsifiers.

In microbiological eczemas, pathogenic and apathogenic germs play a part. There are considerable differences in opinion concerning the significance of microbiological eczemas in metalworking. One question is whether the large

number of germs in water-miscible cutting fluids promote this type of eczema. Some experience indicates that no hygienic risk is posed by germ numbers of 10^5 or 10^6 m/L if no particularly pathogenic germs are present.

Long-term degeneration, for example, caused by exposure to alkalis in water-miscible cutting fluids can ease the ingress of allergens into the skin and thus start the oversensitivity process.

Allergic skin diseases are relatively seldom in metalworking companies. However, the increasing number of chemically active substances in cutting fluids may increase the oversensitivity of skin. Such substances are often found in biocides, EP additives, and corrosion inhibitors.

1. Inorganic Phosphors

1.1. Introduction

Inorganic luminescent materials are synthetically produced crystalline compounds that absorb energy acting on them and subsequently emit this absorbed energy as light, either immediately or over a longer period, in excess of thermal radiation. This light emission, for which, in contrast to thermal radiation, the exciting energy first does not contribute to the thermal energy of the compound, is known as luminescence. It arises from excited states in atoms or molecules which have a lifetime of at least 10^{-9} s. This means that between excitation and ligh emission there is a time span of 10^{-9} s. It is in this respect that luminescence differs from the other luminous effects that, like luminescence, are also not classified as thermal radiation; these include light scattering, the Raman effect, and Cherenkov radiation.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_519

Of the various possibilities for classifying inorganic luminescent materials, categorization according to families of substances is generally preferred, because it permits a clearer presentation of the whole field than the classification according to luminescent effects, such as, for example, the various decay times.

Luminescent inorganic compounds are also known as luminophors and phosphors. Depending on the nature of the exciting energy, the resulting luminescence is named as follows:

Low energy photons	photoluminescence
Cathode rays	cathodoluminescence
X-rays	X-ray luminescence
Ions (particles)	ionoluminescence
Mechanical forces	triboluminescence
Electric field strength	electroluminescence
Chemical reactions	chemiluminescence
Biochemical reactions	bioluminescence

Light emission occurring during excitation and up to ca. 10^{-8} s afterwards is called fluorescence, while the glow continuing longer than 10^{-8} s is known as afterglow or phosphorescence. The decay time is the time in which the brightness decreases to 1/10 or 1/e of the initial intensity, for hyperbolic and exponential decay, respectively.

Certain compounds store the absorbed energy over a longer period and only emit it as light under the influence of heat or IR radiation. This process is called stimulation. The opposite phenomenon, in which the light emission is decreased by the action of heat or IR radiation on luminescent materials, is known as quenching.

History. Various reports indicate that luminescent inorganic compounds were already known in antiquity. Titus Livius (Livy) reports in his book "History of the Romans" that in 186 B.C. the maenads in the bacchanalia had "glowing torches" in their hair, which they then threw into the Tiber. Jorrisson assumes that this was luminescence from calcium sulfide [9].

One of the first reports of the synthesis of a luminescent material dates from 1603, when Casciavolus attempted to obtain gold by heating certain minerals, but instead obtained a rock that emitted reddish light in the dark. Here barium sulfide was formed by reduction of rock containing barium sulfate.

In 1609 Brand discovered a substance that glows brightly in air and named it phosphorus. Since then inorganic luminescent pigments have been named phosphors and their luminescence, phosphorescence. In the 1600 s and 1700 s, many other researchers investigated this light phenomenon, including Goethe.

The systematic scientific investigation of inorganic phosphors only began, however, in the 1800 s with Becquerel, Verneuil, Lenard, and Stokes. Stokes published the first definition of fluorescence in 1852, and drew up the law stating that the exciting light always has a shorter wavelength than the emitted light.

In 1866 Sidot discovered the luminescence of zinc sulfide, which has been the basis of many important industrial phosphors.

In 1867 Bequerel postulated two types of afterglow based on his investigations of uranyl salts: one with exponential and the other with hyperbolic decay.

In 1895 Röntgen used "barium platinocyanate" to make X-rays visible. This discovery led to the first industrial breakthrough for inorganic phosphors. In 1887 Ver-neuil recognized the significance of heavy-metal impurities for the luminescence of inorganic compounds.

In the 1900 s inorganic phosphors gained increasing scientific and industrial interest. In 1903 and 1904 Lenard and Klatt reported the connection between activators and light emission [10]. They were also the first to use fluxes for crystallization and to discuss how they function. The first experiments on producing luminescence solely by the action of an applied electric field were carried out by Gudden and Pohl in 1920 [11], Lossew in 1923 [12], and Destriau in 1936 [13]. Urbach (1926) [14] and Randall and Wilken (1945) [15] traced the different time constants for the decay of the afterglow back to the differing depth of traps.

In 1938/1939 Seitz [16] and Mott [17] developed the electron configuration diagram, on the basis of which, phenomena such as Stokes' Law became understandable.

Using quantum theory, Riehl and Schön, among others, developed in 1939 a model for the luminescence of crystalline phosphors which is essentially still valid [18].

1.2. Luminescence of Crystalline Inorganic Phosphors

1.2.1. Luminescence Processes

The luminescence of inorganic phosphors is comprised of the following processes: 1) absorption and excitation, 2) energy tranfer, and 3) emission.

Excitation requires that energy acts on the phosphor that can be absorbed by it. The excitation mechanism differs, according to the type of energy involved.

Excitation by Photons. The dependence of the absorptivity of a phosphor upon the photon energy is given by the absorption spectrum. This can be divided into various regions such as basic lattice absorption, edge absorption, and defect absorption [8].

Even when all the absorbed photons obey Stokes' Law, the absorption spectrum does not convey what proportion of them contributes to the excitation of photoluminescence. Often, excitation only takes place with photons of higher energy. The absorption that is effective for excitation of luminescence is given by the excitation spectrum, which shows the dependence of the luminescence intensity on the photon energy. Strong luminescence occurs when the exciting photon has sufficient energy to promote an electron from the valence band to the conduction band (see Section 1.2.2.2).

Phosphors that do not effectively absorb photons of a specific energy can often be sensitized for this radiation by incorporation of certain ions with higher absorption for this radiation in the host crystal.

Excitation by Electrons. A portion of the electrons impinging on a phosphor are backscattered elastically with loss of energy. The backscattering factor η and the averaged atomic number $\bar{Z}$ of the atoms are related by [19]

$$\eta = \left(\ln\bar{Z} - 1.5\right)/6$$

For phosphors based on zinc sulfide ($Z_{\mathrm{Zn}} = 30, Z_{\mathrm{S}} = 16$; hence, $\bar{Z}_{\mathrm{ZnS}} = 23$) this gives a backscattering coefficient $\eta \approx 0.27$. This means that 27 % of the energy supplied is not available for luminescence. The effect of the electron energy on backscattering is described in [20].

The electrons that are not scattered elastically lose their energy on penetrating a phosphor crystal by inelastic scattering and formation of secondary electrons.

An expression for the specific energy loss $\mathrm{d}E/\mathrm{d}x$, i.e., the decrease in energy of the primary electron after traveling a distance x in the phosphor, is given by [21]

$$-\frac{\mathrm{d}E}{\mathrm{d}x} = \frac{2\pi N Z e^4}{E} \ln\left(\frac{E}{E_{\mathrm{i}}}\right)$$

where E is the electron energy, N the number of electrons per cm^3, Z the atomic number, e the electronic charge, and E_{i} the average ionization energy of all the electrons. A detailed presentation of this process in the case of cathode-ray excitation is given in [22, 23]. For primary electrons of higher energy (>30 keV), the penetration depth of an electron is given by the Thomson – Whidelington law as

$$\mathrm{E}^2 - E_x^2 = ax$$

where E is the initial energy of the primary electrons, E_x is the energy of the electron after traveling a distance x, and a is a constant. The total penetration depth R is given by $E_x = 0$ and $x = R$, thus: $E^2 = aR$. The range is therefore proportional to the square of the initial energy of the primary electrons.

The inelastically scattered electrons and the secondary electrons produce charge carriers in the phosphor, which then recombine with emission of luminescent radiation, either directly or after traveling in the lattice.

Excitation by X-Rays. As forms of electromagnetic radiation, X- and γ-rays follow the same absorption rules as photons. Because of the high energy of the secondary electrons formed on absorption, however, the excitation mechanism more closely resembles electron excitation than photon excitation. The absorption is given by

$$I = I_0 \mathrm{e}^{-\mu x}$$

where I_0 is the intensity of the incident X-rays, μ is the absorption of the radiation per centimeter, and x is the distance traveled in the material in centimeters.

In practice the mass extinction coefficient μ/ϱ (ϱ = density of the material) is used instead of the absorption coefficient μ.

The X-ray quanta absorbed by a phosphor mainly produce photoelectrons whose kinetic energy is at most equal to that of the absorbed X-ray quanta. In addition, Compton scattering and pair formation occur. The subsequent processes then continue as in electron excitation.

Energy Transfer. The excitation of phosphors does not always take place at the luminescence center but also at other locations in the crystal. A recombination and the associated emission require a transfer of the absorbed energy to the luminescence center. This can take place by the following mechanisms:

1) migration of excited electrons and electron holes,
2) migration of excitons (electron – hole pairs),
3) resonance between atoms with overlapping electric fields, and
4) reabsorption of a light quantum emitted from one activator center by another emission center.

The recombination processes are to a great extent independent of the nature of the excitation. The only parameters that are influenced by the type of excitation are the relative intensities of the various emission bands, the quantum yields, and the decay behavior. For photon excitation, the quantum yield can be up to 70 %, whereas it reaches a maximum of 25 % for electron excitation. The afterglow time and afterglow intensity are lower for electron excitation than for photon excitation.

The simplest case of reaction kinetics occurs when the excitation and emission occur in the same atom, molecule, or luminescence center. The recombination can then be treated as a first-order unimolecular reaction. The decrease in the number of excited electrons is given by:

$$\mathrm{d}n/n = -\lambda dt.$$

The number of excited electrons as a function of time is thus

$$n = n_0 \cdot e^{-\lambda t} \text{ where } \lambda = c/k$$

and the luminescence intensity is given by

$$I = I_0 \cdot e^{-\lambda t}.$$

The decay time is therefore independent of the number of other similarly excited atoms or molecules. If the recombination is delayed, e.g., by migration of excited electrons, luminescence takes place by a second-order bimolecular reaction. The probability of a luminescent recombination of the excited electron with the holes is then proportional to the product of the concentration n of electrons and the concentration p of holes. When $n = p$, $I = -k\,\mathrm{d}n/\mathrm{d}t = cnp = cn^2$ and

$$I = \frac{I_0}{(1+t/\tau)^2} \text{ where } \tau = \frac{k}{\sqrt{cI_0}}.$$

It follows that the lower the initial intensity is, and the further the decay has progressed, the slower the decay to the half value is.

This hyperbolic decay law is only of limited validity. If the excited electron is momentarily trapped before recombination, very complex interactions can arise.

1.2.2. Models of Luminescent Systems

In many cases, luminescence mechanisms are not understood in detail; therefore, simplified and thus generally applicable models are used for their interpretation.

1.2.2.1. Energy Configuration Diagram

This model, based on the energy level diagrams of atoms and molecules, is applicable to luminescence processes in which excitation and emission take place at the same luminescence center, as in the case of gases and organic molecules.

The energy relationships in a luminescence process are presented in a configurational coordinate diagram (Fig. 1). This illustrates the relationship between the potential energy E of the luminescence center (ordinate) and a space coordinate (abscissa), which gives the representative separation between the atom involved and its nearest neighbors or the deflection from its spatial equilibrium position.

Figure 1. Configurational-coordinate diagram

The lower curve represents the ground state of the luminescence center with the vibrational levels, and the upper curve the excited state.

By absorbing exciting radiation the electrons are raised from the ground state to the excited state. These transitions take place so rapidly (10^{-9} s) that no displacement of the atomic nuclei occurs (Franck – Condon principle).

The space coordinate thus remains unchanged and the transitions can be represented by vertical lines. Because the excited system is not immediately in a state of equilibrium after absorption of energy, it first moves towards the lowest vibrational level with loss of energy to the lattice (lattice relaxation). From there the electrons can return to one of the vibrational levels of the ground state with emission of light and finally relax to the equilibrium position. The model explains the band form of the absorption and emission by the distribution over the vibrational levels and the Stokes' shift by means of nonradiative relaxation processes.

If an electron reaches the energy corresponding to the overlap point X of the curves for the excited and ground states by means of absorption and thermal activation, it can cross over into a vibrational level of the same energy in the ground state and subsequently lose the entire excitation energy nonradiatively by relaxation. Higher temperatures therefore reduce the luminescence quantum yield.

Since the excited electrons are captured by the luminescence center, this model does not account for phosphors in which photoconductivity occurs during the excitation.

Activated silicates, halides, halophosphates, uranyl compounds, and barium tetracyanoplatinate are examples of phosphors whose luminescence is explained by the configurational-coordinate diagram. The activator-free tungstates, molybdates and vanadates also belong to this class.

1.2.2.2. Energy Band Model

For many luminescent substances, excitation and emission do not take place within one atom or molecule. In these cases the energy band model is used.

In a crystal, the outer electrons can no longer be assigned to individual atoms but only to the whole crystal lattice. The interaction in the crystal leads to a splitting of the atomic orbitals into energy bands. At low temperatures, the highest completely occupied valence band is separated from the energetically lowest unoccupied conduction band by the forbidden zone, in which in ideal crystals, there are no allowed states. For real crystals, in which the periodic sequence of the crystal unit cells is distorted by lattice defects or impurity ions, discrete energy levels can develop in this forbidden zone. The energy levels near the valence band are termed donor levels, and those near the conduction band, acceptor levels or traps (Fig. 2, see next page).

By absorption of radiation with sufficient energy, an electron is promoted from the valence band to the conduction band (a), where it relaxes to the band edge with radiationless loss of energy to the lattice (d). The positive hole in the valence band is immediately filled by an electron from a donor level (b, c, i). In the case of fluorescence, a radiant transition of the electron from the conduction band to the positive hole formed in the activator level takes place (e). The wavelength of the emitted light is given by the energy difference between the band edge of the conduction band and the activator level.

Figure 2. Energy level diagram for a phosphor

Before recombination, the electron can, however, also be captured nonradiatively by traps (f), from which it is only liberated by input of thermal energy or by absorption of long-wavelength radiation (g). Then, having been retarded, it recombines with the emission of light (h, phosphorescence, stimulated luminescence).

Unoccupied deep traps act as quenching centers and reduce the luminescence because the probability of a transition into the conduction band is lower than that for a radiationless recombination with an electron hole in the valence band. The causes of these types of quenching centers can be particular impurities in the crystal (killers) or lattice deformations brought about mechanically.

Most sulfides belong to the group of phosphors with delocalized luminescence processes, to which the band model can be applied.

Rare-Earth Activators. Phosphors activated by rare earth ions exhibit some peculiarities. In the energy level diagram of the rare earths, luminescence processes often correspond to electron transitions within the incompletely filled $4f$ shell, which is extensively shielded from the crystal field splitting that results from incorporation into a host lattice. Consequently, these phosphors have narrow band spectra, which are to a great extent independent of the nature of the host lattice. The sharp, discrete bands give rise to luminescence colors with high saturation. Because of the low interaction with the crystal lattice, the luminescence quantum yield of phosphors activated with rare earths is often high, and, compared with other phosphors, quenching occurs only at higher temperatures or higher activator concentrations. Europium, terbium, cerium, and neodymium are of industrial interest as activators. Ytterbium, terbium, and praseodymium are also used as sensitizers [24–26].

Multiphoton Phosphors. The particular electronic structure of the rare earths is such that they exhibit several sharp energy levels

when behaving as activators. This permits the energy from two or more photons in succession to be transmitted to one luminescence center. The excited electron thus reaches an even higher energy level.

When the electron returns from this higher level to the ground state, a photon with about twice the energy of the exciting photon is emitted. In this way it is possible to convert IR radiation into visible light. This effect is falsely termed Anti-Stokes' luminescence because no account is taken of the fact that the prerequisite for the emission of the high-energy light quanta is the previous excitation by two or more photons, whose combined energy is greater than that of the light quanta emitted, as Stokes' law requires. The low probability of a transition from the first metastable excited state to the doubly excited state means that the quantum yield is usually low. Alkali and alkaline-earth metal halides, and the halides, oxyhalides, and oxysulfides of yttrium and lanthanum are principally used as the base material, while Er^{3+}, Ho^{3+}, and Tm^{3+} serve as activators. The quantum yield is considerably increased by the addition of Yb^{3+} as sensitizer.

The luminescence processes can be best understood by means of the energy level diagram. Figure 3 shows the transitions for a phosphor with ytterbium as sensitizer and erbium as activator. When subjected to IR radiation, an electron from the ytterbium ground state $^2F_{7/2}$ is promoted to the excited $^2F_{5/2}$ state. The energy of the excited Yb^{3+} is transferred to Er^{3+} and promotes an electron from the ground state to the $^4I_{11/2}$ state. By further energy transfer, the electron reaches the metastable $^4F_{7/2}$ level. From here the electron first passes back to the level $^4S_{3/2}$ nonradiatively and then returns to the ground state $^4I_{15/2}$ with the emission of green light. For a specific phosphor, the emission spectra for single-photon excitation (e.g., UV) and multiphoton excitation are the same.

Some multiphoton phosphors for the conversion of IR into visible light are as follows: $BaYb_2F_8$:Er [27], $Cs_2Na(Er, Yb, Y)Cl_6$ [28], $NaLnF_4$:Yb, Er (Ln = Y, Gd, La) [29], LaF_3:Yb, Er [30], $BaYF_5$:Yb, Er [31], YOCl: Yb, Er [32], $(Y, Yb, Er)F_3$ [33], $CdF_2 \cdot YbF_3 \cdot ErF_3$ [34], and glass ceramics [35].

Figure 3. Multiphoton excitation, energy level diagram

Raw materials of very high purity (min. 99.99 %) are needed for the production of effective multiphoton phosphors since even traces of impurities lead to side reactions, which reduce the already low quantum yields still further.

The starting materials for halides are mostly mixtures of the corresponding oxides or oxalates, which are treated with very high purity hydrochloric or hydrofluoric acid.

The sensitizer content (Yb^{3+}) can be up to 0.5 mol % and the activator content (Er^{3+}, Tm^{3+}), up to 0.05 mol %. After washing and filtration the halides are then heated in N_2, Ar, HF or HCl to 600 – 1100 °C and fired for several hours at this temperature. It is advantageous to

add NH_4F or NH_4Cl to the firing mixture [27–34].

In many cases the multiphoton phosphors are used as single crystals, produced by the Bridgman process. Because of their relatively low efficiency, the industrial application of these phosphors is limited to use in IR radiation detectors (see Section 1.4.7).

1.3. Preparation and Properties of Inorganic Phosphors

1.3.1. Sulfides and Selenides

1.3.1.1. Zinc and Cadmium Sulfides and Sulfoselenides

The raw materials for the production of sulfide phosphors are high-purity zinc and cadmium sulfides, which are precipitated from purified salt solutions by hydrogen sulfide or ammonium sulfide [2,7,8,36]. The concentration of contaminants such as Fe, Co, or Ni must be below 1 % of the activator concentration. The $Zn_{1-x}Cd_xS$ can be produced by mixing precipitated zinc sulfide and cadmium sulfide. However, coprecipitation from mixed zinc – cadmium salt solutions is preferred because of the better homogeneity.

The most important activators for sulfide phosphors are copper and silver, followed by manganese, gold, rare earths, and zinc. The charge compensation of the host lattice is effected by coupled substitution with mono- or trivalent ions (e.g., Cl^- or Al^{3+}). In addition, disorders, such as unoccupied sulfur positions, can also contribute to charge compensation.

For the synthesis of phosphors, the sulfides are homogenized with readily decomposed compounds of the activators and coactivators in the presence of a flux and are fired in quartz crucibles at 800 – 1200 °C.

The luminescent properties can be influenced by the nature of the activators and coactivators, their concentrations, the composition of the flux, and the firing conditions. In addition, specific substitution of zinc or sulfur in the host lattice by cadmium or selenium is possible, which also influences the luminescent properties. The crystal lattice of zinc sulfide is also of influence. It is dimorphic and crystallizes below 1020 °C in the cubic zinc-blende structure and above that temperature in the hexagonal wurtzite lattice. When the zinc is replaced by cadmium, the transition temperature is lowered so that the hexagonal modification predominates. Substitution of sulfur by selenium, on the other hand, stabilizes the zinc blende lattice.

The $Zn_{1-x}Cd_xS$ phosphors have found the greatest industrial use.

Self-activation. Although pure substances do not normally luminesce, zinc sulfide that has been fired in the presence of a halogen luminesces bright blue [37,38]. The luminescence center for activator-free zinc sulfide is assumed to be a cation vacancy. The charge compensation occurs through exchange of S^{2-} by Cl^-.

Cation holes can also be created by coactivation with trivalent metal ions or by incorporation of oxygen [39]. The luminescence band of self-activated zinc sulfide with the zinc-blende structure exhibits a maximum at 470 nm. On transition to the wurtzite structure, the maximum shifts to shorter wavelengths. In the mixed crystals zinc sulfide – cadmium sulfide and zinc sulfide–zinc selenide, the maximum shifts to longer wavelengths with increasing cadmium or selenium concentration (Fig. 4).

Figure 4. Spectra of self-activated $Zn_{1-x}Cd_xS$ phosphors a) $x = 0$, hexagonal; b) $x = 0$, cubic; c) $x = 0.1$; d) $x = 0.2$; e) $x = 0.3$; f) $x = 0.4$; g) $x = 0.5$

Silver Activation. Doping zinc sulfide with silver leads to the appearance of an intense emission band in the blue region of the spectrum at 440 nm, which has a short decay time.

Weak luminescence in the green (520 nm) and red regions can also occur. The blue band is assigned to recombination at substitutionally incorporated silver ions [40,41]. The red band is caused by luminescence processes in associates of silver ions occupying zinc positions

with neighboring sulfur vacancies [42], whereas the nature of the green luminescence center is as yet unknown [43].

Industrial silver-activated zinc sulfide phosphors use the intense blue emission exclusively. The ZnS:Ag phosphor for cathode ray tubes is obtained by firing zinc sulfide and silver nitrate at ca. 1000 °C in the presence of sodium chloride (coactivator Cl^-) [44]. The afterglow can be further reduced by addition of 10^{-3} – 10^{-4} % of nickel ions.

The substitution of zinc by cadmium in the ZnS:Ag phosphor leads to a shift of the emission maximum from the blue over to the green, yellow, red to the IR spectral region (Fig. 5) [8, 45–48].

Figure 5. Spectra of silver-activated $Zn_{1-x}Cd_xS$ phosphors (10^{-2} wt % Ag)

Copper Activation. Activation with copper causes an emission in zinc sulfide which consists of a blue (460 nm) and a green band (525 nm) in varying ratios, depending on the preparation. The green band is assigned to monovalent copper ions incorporated into the host lattice by substitution in the zinc positions, with halide ions acting as coactivators. The blue band is attributed to associates between Cu^+ ions occupying Zn^{2+} positions and interstitially incorporated Cu^+ ions [49–51]. The phosphor ZnS:Cu can also exhibit luminescence in the red or infrared spectral region, depending on the preparation. The red emission band is assigned to a Cu^+ ion associated with a sulfur vacancy [52].

Usually, green-emitting ZnS:Cu phosphors are used for industrial applications. The preparation consists of firing a mixture of ZnS, $Cu(NO_3)_2 \cdot 6\,H_2O$ (corresponding to 50 – 1000 ppm Cu in the phosphor), and 5 wt % NaCl at 900 – 1000 °C in covered fused silica crucibles [53].

The decay time increases with the copper concentration and can be increased to several hours by adding small quantities of cobalt (Fig. 6) (see Section 1.4.4 and 1.4.5). The decay time can be shortened by addition of nickel. It is thus possible to adapt the decay times of copper-doped zinc sulfides to various requirements. The distance between the valence and conduction bands is altered by partial substitution of Zn^{2+} by Cd^{2+}, and of S^{2-} by Se^{2-}. In this way the emission spectrum can be adjusted (Figs. 7 and 8, see next page).

Figure 6. Decay curves of some commercial long-afterglow phosphors
—- LUMILUX Green N; –·–·LUMILUX Green N 5; - - - - LUMILUX Green N 10

Other Activation. Zinc sulfide forms a wide range of substitutionally mixed crystals with manganese sulfide. Manganese-activated zinc sulfide has an emission band in the yellow spectral region at 580 nm [54]. This band can be assigned to the inner transitions of the Mn^{2+} ions incorporated into zinc positions. At higher manganese concentrations, a spectral shift into the orange region takes place as a result of manganese – manganese interactions. At high manganese concentrations, excitation by means of an electric field is possible.

The activation of zinc sulfide with gold leads to luminescence in the yellow-green (550 nm) or blue (480 nm) spectral regions [43, 55–58], depending on the preparation, whereas a blue-white luminescing phosphor is formed on activation with phosphorus [59].

Figure 7. Spectra of copper-activated $Zn_{1-x}Cd_xS$ phosphors (5×10^{-3} wt % Cu)
a) $x = 0$; b) $x = 0.1$; c) $x = 0.2$; d) $x = 0.3$; e) $x = 0.4$

Figure 8. Spectra of copper-activated $ZnS_{1-x}Se_x$ phosphors (5×10^{-3} wt % Cu)
a) $x = 0$; b) $x = 0.2$; c) $x = 0.4$; d) $x = 1$

Multiple activation of zinc sulfide is also possible. Zinc – cadmium sulfide, doubly activated with silver and gold, which is used as a white-luminescing one-component phosphor for monochromic cathode-ray tubes [60], and the yellow-luminescing ZnS:Cu, Au, Al phosphor, whose emission color corresponds to that of Zn_{1-x} Cd_x S:Cu [58], are known.

1.3.1.2. Alkaline-Earth Sulfides and Sulfoselenides

Activated alkaline-earth metal sulfides have been known for a long time; their luminesence is very varied. Emission bands between the ultraviolet and near infrared can be realized by varying the activation [61–65]. They are produced by precipitation of sulfates or selenites from purified solutions, followed by reduction with Ar – H_2. The addition of activators, for example, copper nitrate, manganese sulfate, or bismuth nitrate, is followed by firing for 1 – 2 h. Alkaline-earth halides or alkali-metal sulfates are sometimes added as fluxes.

Among the long afterglow alkaline-earth sulfides, only (Ca, Sr)S:Bi^{3+} and CaS:Bi^{3+} still have any real importance because their respective blue and violet luminescence cannot yet be achieved with the less hydrolysis-sensitive zinc sulfide phosphors.

The alkaline-earth sulfides activated with rare earths are of greater importance. These phosphors are considered suitable for use in cathode-ray tubes because of the linear dependence of their brightness on current over a wide range [61–68]. The emission band of MgS with 0.004 mol % europium has a maximum at 600 nm, whose cathode-ray brightness reaches or surpasses that of $Y_2O_2S:Eu^{3+}$. On substitution of magnesium by calcium, a nonlinear shift of the emission maximum occurs ($Ca_{0.4}Mg_{0.6}S:Eu^{2+}$, $\lambda_{max} = 668$ nm, $CaS:Eu^{2+}$, $\lambda_{max} = 650$ nm) but at the same time there is a decrease in brightness [69].

$CaS:Ce^{3+}$ is a green-emitting phosphor. On activation with 10^{-4} mol % cerium, the emission maximum occurs at 540 nm. Greater activator concentrations lead to a red shift; substitution of calcium by strontium, on the other hand, leads to a blue shift; $SrS:Ce^{3+}$ (10^{-4} mol % cerium) has $\lambda_{max} = 483$ nm [70].

$MgS:Ce^{3+}$ (0.1 %) has two emission bands in the green and red spectral regions at 525 and 590 nm; $MgS:Sm^{3+}$ (0.1 %) has three emission bands at 575 nm (green), 610 (red), and 660 nm (red) [66].

Calcium or strontium sulfides, doubly activated with europium – samarium or cerium – samarium, can be stimulated by IR radiation (see Section 1.4.7), since Sm^{3+} acts as a trap through the transition $Sm^{3+} + e^- \rightarrow Sm^{2+}$ [67]. Emission occurs at europium or cerium and leads to orange-red ($SrS:Eu^{2+}, Sm^{3+}$) or green ($CaS:Ce^{3+}, Sm^{3+}$) luminescence.

1.3.2. Oxysulfides

Red-emitting $Y_2O_2S:Eu^{3+}$ phosphors were developed especially for excitation with cathode rays [71, 72]. Production generally starts from the mixed rare-earth oxides, which are fired with sodium carbonate and sulfur. The polysulfide formed acts as a flux and sulfurizing agent [73]. The addition of a small amount of terbium sensitizes the europium luminescence [74].

The main emission lines of $Y_2O_2S:Eu^{3+}$ occur at 565 and 627 nm. The intensity of the long-wavelength emission increases with the europium concentration, whereby the color of the emission shifts from orange to deep red. For use in color picture tubes, $Y_2O_2S:Eu^{3+}$ (see Section 1.4.3) contains ca. 4 wt % europium [75]; $Y_2O_2S:Eu^{3+}$ is unsuitable for use in lamps because of extensive thermal quenching of the luminescence above room temperature. Terbium in Y_2O_2S has main emission bands in the blue (489 nm) and green spectral regions (545 and 587 nm), whose intensity ratio depends on the terbium concentration. At low doping levels, $Y_2O_2S:Tb^{3+}$ luminesces blue-white, while at higher levels the color tends towards green. Although $Y_2O_2S:Tb^{3+}$ has been used for X-ray intensifying screens, $Gd_2O_2S:Tb^{3+}$, which also exhibits green luminescence, is predominantly used in X-ray technology because of its higher absorption. White luminescence for use in special cathode-ray tubes can be achieved with blends of Y_2O_2S:Tb and Y_2O_2S:Eu [76] or by double activation of Y_2O_2S with terbium and europium [77].

1.3.3. Oxygen-Dominant Phosphors

Oxygen-dominant phosphors are generally produced by solid-state reactions in which the components of the phosphor (mostly oxides) are intimately mixed and fired at 500 – 1500 °C. The desired phosphor is formed by solid-state reaction below the melting point of the compound during a firing period of 3 – 16 h.

The Tamman rule, which states that a measurable rate of change of position of the lattice components begins at two-thirds of the absolute melting point, gives an indication of the necessary firing temperature [78].

The activators are added in the form of oxides, oxalates, carbonates, or other compounds which readily decompose at higher temperatures.

The oxidation state of the activators can be influenced by the choice of the furnace atmosphere. As in the case of the sulfide phosphors, contamination by Fe, Co, or Ni greatly reduces the quantum yield.

As well as higher quantum yields, oxygen-dominant phosphors stand out because of their good temperature stability. For most substances the quantum yield only decreases noticeably above 250 °C.

1.3.3.1. Borates

Strontium fluoroborate $Sr_3B_{12}O_{20}F_2$: Eu^{2+} is used in photocopier lamps, black light lamps, and lamps for medical applications (λ_{max} = 366 nm).

It is produced by the addition of aqueous ammonia to an aqueous solution of $Eu(NO_3)_3$, $Sr(NO_3)_2$, and H_3BO_3 at 95 °C and pH 8 to precipitate europium-containing $SrB_6O_{10}\cdot 5\,H_2O$. The latter is mixed with SrF_2 and, after a preliminary reaction at 400 °C, is fired at 820 °C in air and then at 900 °C under N_2– H_2 (95/5) [79].

1.3.3.2. Aluminates

Yttrium aluminate $Y_3Al_5O_{12}:Ce^{3+}$ (YAG) is produced by precipitation of the hydroxides with NH_4OH from a solution of the nitrates and subsequent firing at 1450 °C [80]. To enable a lower reaction temperature of 1300 °C to be used, a freeze-dried powder is also used, which is produced from a solution of $(NH_4)_2Ce(NO_3)_6$, $Al_2(SO_4)_3\cdot 18\,H_2O$, and $Y_2(SO_4)_3$ [81].

The solubility of Ce^{3+} in $Y_3Al_5O_{12}$ depends on the atmosphere in which the mixture is fired. At 1450 °C in a hydrogen atmosphere, up to 6 mol % Ce^{3+} can be incorporated into the $Y_3Al_5O_{12}$ lattice. At higher concentrations, $CeAlO_3$ is formed as a second phase. At 1450 °C in air the solubility is only 2 mol %; higher concentrations lead to CeO_2 as the second phase. In each case the cerium is incorporated as Ce^{3+} [81].

When fired in a reducing atmosphere, $Y_3Al_5O_{12}$ exhibits a pronounced afterglow due to traps formed by oxygen vacancies [82]. Subsequent annealing in air diminishes this effect and leads to decay times of 200 – 300 ns; therefore, $Y_3Al_5O_{12}:Ce^{3+}$ is used in flying-spot scanner tubes. The emission maximum is at 550 nm. This phosphor is classified under P 46 (TEPAC) and KG (WTDS) (see Section 1.4.3).

Cerium magnesium aluminate (CAT) $Ce_{0.65}Tb_{0.35}MgAl_{11}O_{19}$ is produced by coprecipitation of the metal hydroxides from a so-

lution of the nitrates with NH_4OH and subsequent firing at 700 °C for 2 h followed by 1 h at 1500 °C [83]. Another possibility is to fire a mixture of Al_2O_3, $MgCO_3$, CeO_2, and Tb_4O_7 for 5 h at 1500 °C with small quantities of MgF_2 or AlF_3 as a crystallizing agent [83]. A strongly reducing atmosphere is necessary to ensure that the rare earths are present as Ce^{3+} and Tb^{3+}.

Cerium magnesium aluminate is a highly efficient green phosphor ($\lambda_{max.} = 541$ nm), which is used in trichromatic fluorescent lamps. The high quantum yield of 65 % is effected by the energy transfer from the sensitizer, Ce^{3+}, to the activator, Tb^{3+}.

Barium magnesium aluminate (BAM) $BaMg_2Al_{16}O_{27}$:Eu^{2+} is produced by firing a mixture of Al_2O_3, $BaCO_3$, $MgCO_3$, and Eu_2O_3 in the presence of a flux in a weakly reducing atmosphere at 1100 – 1200 °C [84]. It is used as the blue component ($\lambda_{max} = 447$ nm) in trichromatic fluorescent lamps.

Yttrium aluminum gallium garnet (YAGG) $Y_2Al_3Ga_2O_{12}$:Tb^{3+} [85] can be produced by mixing a stoichiometric quantity of the oxides (5 – 7 mol % terbium) with 20 % BaF_2 in ethanol. After drying, the mixture is fired for 2 h at 1500 °C. The flux is washed out with 20 % nitric acid. Yttrium aluminum gallium garnet is a green phosphor with high brightness for use in projection television tubes. It does not show any saturation even at high current densities of 160 μA/cm^2.

For the mixed aluminate – gallate, the attainable brightness shows a greater dependency on the firing temperature than is the case with pure aluminate or gallate. Differences of 100 °C in the firing temperature reduce the brightness by 25 –40 %.

1.3.3.3. Gallates

Strontium thiogallate is produced by firing a mixture of high-purity sulfides in a stream of hydrogen sulfide at 900 – 950 °C for 2 h; Pb^{2+} and Ce^{3+} (with Na^+ for charge compensation) are used as activators [86, 87].

$SrGa_2S_4$:Ce^{3+}, Na^+ with 4 mol % cerium ($\lambda_{max.} = 455$ nm, $\eta = 5.0$ %) and $SrGa_2S_4$:Pb^{2+} with 8 mol % lead ($\lambda_{max.} = 595$ nm, $\eta = 4.6$ %) are used in flying-spot scanner tubes (see Section 1.4.3) because of their short decay times (I_0/100) of 1.55 μs and 1.24 μs, respectively. Their low ageing upon electron beam bombardment is also noteworthy. Because of the relatively broad emission bands, a blend of 15 wt % $SrGa_2S_4$: Ce^{3+}, Na^+ with 85 wt % $SrGa_2S_4$: Pb^{2+} gives an extensive, regular emission throughout the visible spectrum (Fig. 9) [88].

Figure 9. Spectrum of phosphor blend $SrGa_2S_4$:Ce + $SrGa_2S_4$:Pb (15/85)

1.3.3.4. Silicates

Zinc orthosilicate Zn_2SiO_4:Mn^{2+} can be produced by firing a mixture of ZnO, SiO_2, and $MnCO_3$ at 1200 °C for 2 h. Small quantities of MgF_2 or ZnF_2 accelerate the reaction [7].

$ZnSiO_4$:Mn is used as a green phosphor ($\lambda_{max.} = 525$ nm) in fluorescent lamps and cathode-ray tubes and is cited in the TEPAC list as P 1 and in the WTDS as GJ. Its ability to be excited by low-energy electrons (a few eV), its linear increase in brightness with electron beam intensity, and its high resistance to burn-in, even at high current density, are advantageous. The resistance to burn-in can be improved still further by employing a sol – gel process during the production. This involves reaction of a $[Zn(NH_3)_4](OH)_2$ solution with $Si(OC_2H_5)_4$ to give a gel, which is subsequently dried and fired [5]. The decay time of ca. 30 ms can be increased to the order of minutes by the addition of arsenic (a few ppm to 0.5 wt %) [89].

$ZnSiO_4$:Mn, As is standardized as P 39 in TEPAC and GR in WTDS.

By successive replacement of zinc by beryllium (up to 10 mol %), the red Mn^{2+} line at

610 nm becomes stronger and the line at 525 nm weaker, so that a shift of the emission color into the orange region occurs. Because of the toxicity of beryllium these phosphors are, however, generally no longer used.

Yttrium orthosilicate $Y_2SiO_5:Ce^{3+}$ is used as a highly resistant blue cathode-ray phosphor in projection television tubes ($\eta = 6\,\%$) [90]. It is classified as BH (WTDS) and P 47 (TEPAC). The emission maximum is between 400 nm (0.1 % Ce) and 460 nm (10 % Ce). The production involves firing a mixture of Y_2O_3, SiO_2, and $Ce(SO_4)_2 \cdot 4\,H_2O$ for 16 h at 1250 °C. Further firing for 4 h at 1160 °C in a reducing atmosphere is necessary to bring the cerium into the trivalent state. The addition of NaF or YF_3 improves crystallization. Doping with Tb^{3+} instead of Ce^{3+} leads to an efficient ($\eta = 7\,\%$) green phosphor, in which coactivation by Ce^{3+} can increase the luminescence by a further 10 % [91]. An yttrium orthosilicate doped with Ce, Tb, and Mn, is used in artificial teeth.

The phosphors obtained by solid-state reactions are not sufficiently resistant to ageing for use in fluorescent lamps. In a pseudo-sol – gel process an aqueous solution of (Y, Tb) $(NO_3)_3$ is treated with SiO_2 and heated to 1200 °C. After subsequent reductive firing under N_2/H_2 at 1700 – 1800 °C, a phosphor is obtained with a resistance to ageing comparable to that of the aluminates [92].

Barium disilicate $BaSi_2O_5$:Pb emits in the long-wavelength ultraviolet ($\lambda_{max} = 350$ nm). This phosphor is used in blacklight fluorescent lamps; the quantum yield is 75 %.

The phosphor is produced by stirring $BaCO_3$, BaF_2, $Pb(NO_3)_2$, and SiO_2 (fumed silica) to a slurry in methanol. After drying, the mixture is fired for 30 min at 1050 °C, with the heating up and cooling down between 800 and 1050 °C being carried out at a rate of 200 °C/h [93].

1.3.3.5. Germanates

Magnesium fluorogermanate, $3.5\,MgO \cdot 0.5\,MgF_2 \cdot GeO_2:Mn^{4+}$ is a brilliant red phosphor used in fluorescent lamps [94]. Because of its yellowish color, it strongly absorbs the blue mercury emission lines in these lamps, so that a saturated red light results. The emission maximum lies at 660 nm. The temperature stability of this phosphor is particularly high; therefore, it is used for high-pressure mercury lamps. With rising temperature the absorption edge of the host lattice (350 – 400 nm) shifts to longer wavelengths. Therefore, the brightness increases with increasing temperature up to 300 °C because the mercury line at 365 nm is then absorbed more effectively. The phosphor is produced by firing a stoichiometric mixture of MgO, MgF_2, and GeO_2 with 0.01 mol % $MnCl_2$ for 5 h at 1150 °C in an oxidizing atmosphere [94].

1.3.3.6. Halophosphates and Phosphates

The halophosphates are doubly activated phosphors [95], in which Sb^{3+} and Mn^{2+} function as sensitizer and activator, giving rise to two corresponding maxima in the emission spectrum. The antimony acts equally as sensitizer and activator. It transfers part of its excitation energy to manganese. By changing the activator concentration, the blue antimony emission can be adjusted in favor of the orange-yellow manganese emission in such a way that halophosphates can emit white light of varying color temperature.

Halophosphates crystallize in the apatite structure. The chemical composition can be expressed most clearly as $3\,Ca_3(PO_4)_2 \cdot Ca(F, Cl)_2:Sb^{3+}, Mn^{2+}$.

For many years halophosphates were quantitatively by far the most important group of phosphors for low-pressure mercury discharge lamps (fluorescent lamps). The number of studies on the optimization of the quantum yield of halophosphates is correspondingly large. The most important work on the properties and production technology has been reported, for example in [79, 96].

Halophosphates are produced by the solid-state reaction of high-purity $CaHPO_4$, $CaCO_3$, CaF_2, NH_4Cl, $MnCO_3$, and Sb_2O_3. Because of the volatility of antimony trioxide and to avoid the oxidation of Mn^{2+} and Sb^{3+}, the mixture is usually fired under nitrogen at 1150 – 1200 °C in covered crucibles.

The substitution of a small proportion of the calcium by cadmium gives a considerable improvement in the radiation stability and an improved quantum yield for halophosphates in fluorescent lamps. The formation of undesirable color centers is strongly suppressed by addition

of cadmium [97]. The cadmium presumably accelerates the reaction [98], thus minimizing side reactions during the firing process.

Because of the toxicity of cadmium, its use was abandoned in the 1980 s. Nevertheless, by improving the quality of the raw materials and changing the reaction stoichiometry, it was possible to reproduce the quantum yield of the halophosphates, even without the addition of cadmium [99]. The absorption of the exciting UV radiation is strongly dependent on the particle size of halophosphate phosphors and decreases rapidly for particles larger than 3 µm. The particle size is influenced to some extent by the particle size of raw materials (calcium hydrogen phosphate) in the firing mixture. On the other hand mechanical separation processes (sieves) are used to free the fired product from undesired coarse and fine particles.

The following phosphate phosphors have achieved industrial importance: $(Sr,Mg)_3(PO_4)_2$:Sn^{2+}; $LaPO_4$:Ce^{3+}, Tb^{3+}; $Zn_3(PO_4)_2$: Mn^{2+}; $Cd_5Cl(PO_4)_2$:Mn^{2+}; $Sr_3(PO_4)_2 \cdot SrCl_2$: Eu^{2+}; and $Ba_2P_2O_7$:Ti^{4+}. $(Sr,Mg)_3(PO_4)_2$:Sn^{2+} is used in high-pressure mercury lamps. Absorption takes place by Sn^{2+}. The emission band, with a half-band width of 150 nm, has a maximum at 630 nm. Since only the high temperature form ($\geq$ 1300 °C) exhibits good luminescence, it must be cooled rapidly in a reducing atmosphere after firing. The incorporation of small quantities of Al^{3+}, Mg^{2+}, Zn^{2+}, Ca^{2+}, or Cd^{2+} stabilizes the luminescent high-temperature form. In high-pressure mercury lamps, $(Sr,Mg)_3(PO_4)_2$: Sn^{2+} has been replaced by the more effective YVO_4:Eu^{3+}, Tb^{3+}.

The phosphor $LaPO_4$:Ce^{3+}, Tb^{3+} has assumed importance as the green component in trichromatic fluorescent lamps. The emission maximum is at 544 nm and the excitation maximum at 290 nm. It can be produced by solid-state reaction of La_2O_3, Tb_4O_7, $NH_4H_2PO_4$, and CeO_2 or CeF_4 in a reducing atmosphere at 1000 – 1250 °C. Although $LaPO_4$:Ce^{3+}, Tb^{3+} has a high quantum yield comparable with that of CAT (see Section 1.3.3.2), it is insufficiently stable to oxidation in air. Stabilization by large tetravalent cations (Th^{4+}, U^{4+}) [100] and by Sc^{3+} [101] has been claimed. $Zn_3(PO_4)_2$:Mn, which has an emission maximum at 635 nm, is used as a cathode-ray tube phosphor for data displays under the TEPAC number P 27 and WTDS specification RE. It is produced by solid-state reaction between ZnO, $MnCO_3$, and H_3PO_4 in an aqueous slurry. After drying, firing is carried out at 900 – 1150 °C for several hours in an open crucible [102]. $Cd_5Cl(PO_4)_3$:Mn is a yellow-orange-emitting CRT-phosphor for data displays with the WTDS designation LA. It is produced by solid-state reaction at 750 °C after the components $CdSO_4$, CdO, $MnCl_2$ and $NH_4H_2PO_4$ have undergone preliminary reaction in an aqueous medium [103]. 3 $Sr_3(PO_4)_2 \cdot SrCl_2$:$Eu^{2+}$ can be excited by radiation from the entire UV range. The excitation maximum lies at 375 nm and the emission maximum at 447 nm. Upon successive substitution of Sr^{2+} by Ca^{2+} and Ba^{2+}, the emission maximum shifts to 450 nm. In the preparation, $SrCl_2$ is used in excess to improve the crystallization [104]. The phosphor was used as the blue component in trichromatic fluorescent lamps [105] and in the first generation of compact lamps.

Blue-green emitting $Ba_2P_2O_7$:Ti (λ_{max} = 493 nm) is used as the blue component in mixtures with halophosphates for the adjustment of some cool-white light colors. This phosphor is prepared by firing $BaHPO_4$, TiO_2, and BaF_2 at 1050 °C [105–107].

1.3.3.7. Oxides

Industrially, the most important of this group is Y_2O_3:Eu^{3+}. The preparation is generally carried out by precipitating mixed oxalates from purified solutions of yttrium and europium nitrates. Firing the dried oxalates at ca. 600 °C is followed by crystallization firing at 1400 –1500 °C for several hours [108].

Yttrium oxide and europium oxide form a series of mixed crystals without vacancies because of the small difference between their ionic radii [109, 110]. Y_2O_3:Eu^{3+} shows an intense emission line at 611.5 nm in the red region, corresponding to the transition $^5D_0 \rightarrow {}^7F_2$ in europium. The luminescence of this red emission line increases with increasing Eu concentration up to ca. 10 mol %. The concentration in industrial lamp phosphors is ca. 3 mol %. Small traces of Tb enhance the Eu fluorescence of Y_2O_3:Eu^{3+}. Furthermore, this coactivation leads to a shift of the short-wavelength absorp-

tion edge of the host lattice from 220 (Y_2O_3) to 280 nm [111]. This allows excitation with short wavelength UV; excitation by electrons is also possible (Section 1.4.3). This phosphor for cathode-ray tubes is designated as RE (WTDS) and P 56 (TEPAC). Y_2O_3:Eu^{3+} shows no significant decrease in luminescence brightness up to 500 °C.

ZnO:Zn is a typical example of a self-activated phosphor. In the case of zinc oxide, it is an excess of zinc which enables the phosphor to luminesce. The production is carried out by thermal oxidation of crystallized zinc sulfide in air at ca. 400 °C. The green luminescence, with a broad maximum at 505 nm, has a very short decay time of 10^{-6} s. As a phosphor for cathode-ray tubes, ZnO:Zn is classified in the TEPAC list as P 24 and in the WTDS system as GE.

The compound β-Ga_2O_3:Dy, which has photoluminescence properties but no commercial significance, is described in [112].

1.3.3.8. Arsenates

Magnesium arsenate 6 MgO·As_2O_5:Mn^{4+} is a very brilliant red phosphor used in fluorescent lamps. Because of its yellow color, it absorbs the blue mercury lines from which the strong red of the fluorescent lamp light results. The emission maximum is at 655 nm. The phosphor is best produced from solutions of $MgCl_2$ and $MnCl_2$ by precipitation with pyroarsenic acid. The dried precipitate is fired for at least 8 h at 900 °C. A second firing at 1100 °C for 5 h is carried out in the presence of boric acid to improve the crystallization [113].

Magnesium arsenate has lost its industrial importance because of the toxicity of arsenic.

1.3.3.9. Vanadates

Of the vanadates activated with rare earths, YVO_4:Eu^{3+} [114–116] has found the greatest industrial application. Vanadates with other activators (YVO_4 with Tm, Tb, Ho, Er, Dy, Sm, or In; $GdVO_4$:Eu; $LuVO_4$:Eu) have attracted only scientific interest [117–119].

In YVO_4:Eu^{3+}, the europium emission lines at 619 and 614 nm, due to the transition $^5D_0 \rightarrow {}^7D_0$, are not quenched up to 300 °C. Although quenching occurs at higher temperatures, the main lines still retain 50 % of their intensity at 500 °C. Small quantities of terbium activate the red Eu^{3+} lines at higher temperatures [120].

The long-wavelength absorption edge of YVO_4:Eu^{3+} at 340 nm shifts to longer wavelength with rising temperature. The long-wavelength mercury lines of high-pressure mercury lamps can thus be used for excitation. The incorporation of Bi^{3+} sensitizes the Eu^{3+} emission [121] and results in a shift of the luminescence color towards orange, because the emission line at 565 nm, corresponding to the transition $^5D_0 \rightarrow {}^7F_1$, increases in intensity. YVO_4 forms a series of mixed crystals with the isostructural YPO_4. Successive substitution of VO_4^{3-} by PO_4^{3-} shifts the absorption edge of Y(VO_4, PO_4) at 340 nm to shorter wavelengths and increases the temperature at which thermal quenching occurs.

For the production of YVO_4:Eu, the mixed oxides of yttrium and europium are thoroughly ground with an alkali-metal hydroxide as flux and high-purity NH_4VO_3. In a two-stage firing process with intermediate grinding, the mixture is fired at 600 – 650 °C and then at 1100 – 1200 °C for several hours. Excess alkali-metal vanadate is washed out with dilute sodium hydroxide solution. The effect of the production conditions on the particle size of YVO_4:Eu^{3+} has been studied [122].

1.3.3.10. Niobates and Tantalates

The luminescence of rare-earth tantalates is described in [123]. Tantalates crystallize in three different structures, depending on the cation [124]. Yttrium tantalate and yttrium niobate – tantalate have good X-ray absorption and are used in X-ray intensifying screens because of their high conversion factor (Section 1.4.2.). Substitution of tantalum by small quantities of niobium considerably increases the blue fluorescence when excited by X-rays.

The incorporation of traces of terbium strengthens the green emission band for the so-called M' structure of the tantalate, which exists only below 1325 °C in the monoclinic structure (M' phase) [125]. The advantage of the X-ray excitable tantalates lies in the fact that the emis-

sion spectrum extends into the near UV. The films used with X-ray intensifying screens are particularly sensitive in this region.

The tantalates are produced by a solid-state reaction between Ta_2O_5, Nb_2O_5, and Y_2O_3 in a 14-hour preliminary firing at 1000 °C and a crystallization firing with lithium chloride or lithium sulfate as flux.

1.3.3.11. Sulfates

Without exception, the basic lattice of sulfate phosphors absorbs very short wavelength UV radiation. On excitation with X-rays or radiation from radioactive elements, a large proportion of the energy is stored in deep traps. For this reason, $CaSO_4$:Mn is used in solid-state dosimeters. Of the glowpeaks which can be selected by thermoluminescence, more than 50 % fail to appear at room temperature because of a self selection of the shallow traps. Other activators, such as lead or rare-earth ions (Dy^{3+}, Tm^{3+}, Sm^{3+}), stabilize the trapped electrons [126–128].

Photoluminescent sulfates are obtained by activation with ions that absorb short-wavelength radiation, for example, Ce^{3+}. Alkali-metal and alkaline-earth sulfates with Ce^{3+} emit between 300 and 400 nm. On additional manganese activation, the energy absorbed by Ce^{3+} is transferred to manganese with a shift of the emission into the green to red region. Sulfate phosphors can be produced relatively easily. Water-insoluble sulfates are thoroughly mixed with the activators and fired in covered crucibles below the melting point. In the case of activation by Ce^{3+} and Mn^{2+} the activator concentration is at least 0.5 mol % [129].

Water-soluble sulfates are obtained by evaporating a solution of the mixed salts to dryness.

The luminescence properties of sulfates activated by Ce^{3+} and Mn^{2+} are described in detail in [129].

1.3.3.12. Tungstates and Molybdates

Magnesium tungstate $MgWO_4$ and calcium tungstate $CaWO_4$ are commercially the most important self-activated phosphors. Magnesium tungstate is often used as a reference material for UV-excited phosphors because of its high quantum yield of 84 % for the conversion of the 50–270-nm radiation into visible light; it is cited as standard phosphor 1027 for quantum output by the NBS [130]. The temperature dependence is relatively low; the maximum yield is at 240 K, but is still as high as 50 % at 400 K.

The emission maximum after excitation in a fluorescent lamp is at 482 nm with a half-intensity width of 140 nm. Magnesium tungstate crystallizes in the wolframite structure [131]. On additional activation with rare-earth ions their typical emission also occurs. Calcium tungstate crystallizes with the scheelite structure. Magnesium tungstate is produced by heating an excess of MgO or basic magnesium carbonate with high-purity WO_3 or H_2WO_4 at 1000–1100 °C. Excess MgO is washed out with 10 % hydrochloric acid.

$MgWO_4$ is used in blends with other phosphors in high-voltage advertisement illumination tubes and as a fluorescent material in TLC plates. Because of its high effective absorption of X-rays, $CaWO_4$ is used in large quantities for the production of X-ray intensifying screens in combination with blue-sensitive films. $CaWO_4$:Pb is still used as the blue phosphor in fluorescent lamps.

The production of self-activated $CaWO_4$ is more difficult than that of $MgWO_4$. Small deviations from stoichiometry in the composition have a marked effect on the efficiency. Also, traces of Pb^{2+} shift the emission peak from 415 nm to 439 nm (0.0006 mol % Pb^{2+}). To bind excess CaO in the production process, a small proportion of sulfate is used. The precipitated $CaWO_4$ is washed until chloride-free, dried, and subjected to crystallization firing at 800 °C with 30 % flux. The formation of luminescent $CaWO_4$ from the precipitate is described in [132].

Self-activated molybdate phosphorus are described in [133]. The energy transfer that occurs in molybdates activated with Eu^{3+} is described in [114, 134].

1.3.4. Halide Phosphors

The longest-known luminescent halide is calcium fluoride. The term fluorescence is derived from the naturally occurring luminescent mineral fluorspar.

Table 1. Alkali-metal halide phosphors

Host crystal	Activator		ϱ, g/cm^3	*mp*, °C	Emission peak, nm	Use ∗
	Type	Conc., mol %				
LiI	Eu	$5-6\times10^{-2}$	3.49	449	440	S
NaI	Tl	10^{-1}	3.67	651	410	S
CsI	Tl	10^{-1}	4.51	624	565 – 600	S
CsI	Na	$4-6\times10^{-4}$	4.51	624	430	S
LiF	Mg	$10^{-8}-10^{-2}$	2.63	842	400	TLD
LiF	Mg, Ti	$10^{-3}-10^{-2}$	2.63	842	400	TLD
LiF	Mg, Na	$10^{-3}-10^{-2}$	2.63	842	400	TLD

∗ S = scintillator (see Section 1.4.7); TLD = thermoluminescent dosimeter (see Section 1.4.7).

Alkali-Metal Halides. Luminescent alkali-metal halides can be produced easily in high-purity and as large single crystals. They are therefore often used as model substances for the investigation of luminescence processes. The luminescence processes of the alkali-metal halides can be divided into: 1) the self-luminescence of the undoped crystals, 2) luminescence by lattice defects, and 3) sensitized luminescence.

Self-Luminescence. The action of UV light or ionizing radiation on pure alkali-metal halide crystals causes luminescence which is very intense, particularly at low temperature. The emission spectrum is characteristic for each individual compound. This fluorescence is comparable with the recombination luminescence which occurs upon capture of an electron by a V_K center (defect electron).

Luminescence of Lattice Defects. Many defect centers are known in the case of the alkali-metal halides, which are derived from electrons in anion vacancies (F centers, or color centers). Association of two or more F-centers gives new defect centers, which can each also take up an electron. These lattice defects act as luminescence centers, the emission spectra of which sometimes exhibit a large number of lines.

At certain temperatures phosphorescence can also be observed, which indicates strong relaxation in the excited state.

As well as the F-centers and F-aggregates (M, R, and N centers), there are also various other anion and cation defects which act as luminescence centers.

Foreign-Ion Luminescence. Through the incorporation of foreign ions (e.g., Tl^+, Ga^+, In^+) into the crystal lattice, further luminescence centers are formed. The emission spectra are characteristic for the individual foreign ions. The complicated luminescence mechanism is described in [135].

The alkali-metal halide phosphors are produced by firing the corresponding alkali-metal halide and the activator in platinum or fused-silica crucibles under an inert atmosphere.

Some industrially important alkali-metal halide phosphors are listed in Table 1.

NaI:Tl and CsI:Tl are used as detectors for X- and γ-rays because of their high absorption capacity for these types of radiation. Europium-activated lithium iodide is preferred for neutron detection because of its favorable capture cross section. The phosphor CsI:Na is particularly important industrially as an X-ray converter in optoelectronic image intensifiers (Section 1.4.2). It has a high effective quantum absorption for X-rays of energy 20 – 80 keV, which are used in medicine. Since the vapor pressure curves for CsI and NaI differ only slightly, it is possible to produce luminescent screens with good resolution by evaporation. The emission spectrum of CsI:Na also corresponds well to the spectral sensitivity of the photocathodes usually used for image intensifiers.

Alkaline-Earth Halides. Of the alkaline-earth halide phosphors, those doped with manganese or rare earths have been used industrially (Section 1.4.7) (e.g., CaF_2:Mn; CaF_2:Dy).

On excitation with high-energy radiation these compounds store part of the energy, which can subsequently be "called up" by stimulation. If the stimulation is achieved by heating, the resulting luminescence is termed thermoluminescence.

Thermoluminescent phosphors are used industrially in dosimeters. They are produced by coprecipitation of CaF_2 and an activator from a solution of the corresponding cations, or by the reaction of oxides or carbonates of the cations with hydrofluoric acid followed by firing. Moldings with high transparency for use in dosimeters can be produced by high-temperature pressing.

A further industrially important class of phosphors are the alkaline-earth fluorochlorides. The compound $Ba_{0.95}Eu_{0.05}FCl$ exhibits strong emission, with a peak at 375 nm, on X-ray excitation [136]. Substitution of Cl^- by Br^- shifts the peak to 385 nm. The Eu^{3+} acts as the luminescence center. The production is carried out by grinding BaF_2 with $BaCl_2$ or $BaBr_2$ in the molar ratio 1:1 with 0.04 – 0.07 mol % of a europium trihalide. After drying, the mixture is fired in a reducing atmosphere.

The Ba^{2+} can be completely or partially substituted by Sr^{2+} or Ca^{2+}, and Cl^-, by Br^- or I^-. Information on this and other production processes is given in [137–139]. These phosphors are used in X-ray intensifying screens (Section 1.4.2).

The $BaFBr:Eu^{2+}$ phosphors are gaining increasing industrial importance because of their storage effect. On irradiation with X-rays (or UV light) some of the Eu^{2+} ions are ionized to Eu^{3+} with loss of electrons to the conduction band. These electrons are captured by F^+ centers (anion vacancies) and can be liberated from these traps by the action of light (stimulation). The electrons return to the Eu^{3+} ions via the conduction band, converting them to Eu^{2+} [140–144].

The production of such storage phosphors is carried out by the method described for $BaFCl:Eu^{2+}$. These phosphors are used for storage panels in X-ray diagnostics (see Section 1.4.2).

Other Halide Phosphors. Information on the most important manganese-activated phosphors is summarized in Table 2. These fluorides are produced by the method given below for $(Zn, Mg)F_2:Mn^{2+}$.

MgF_2 and $ZnSO_4$ are made into a paste in the desired molar ratio and a solution of the activator is added. After drying, the mixture is fired in quartz trays above 1000 °C. These orange-emitting phosphors stand out because of their long afterglow time and are therefore still used in special radar tubes and oscilloscopes [7, 8, 145], despite their low stability towards burn-in compared with other cathode-ray phosphors.

Oxyhalides. The oxyhalides of yttrium, lanthanum, and gadolinium are good host lattices for activation with other rare-earth ions such as terbium, cerium, and thulium. The use of $LaOCl:Tb^{3+}$ as the green component in projection-television tubes has been discussed [146]. $LaOBr:Tb^{3+}$ and $LaOBr:Tm^{3+}$ exhibit high X-ray absorption, and, because of the good agreement between the emission spectrum and the spectral sensitivity of the X-ray films, they are used in X-ray intensifying screens [147].

The activator concentration (Tb, Tm) is 0.01 – 0.15 mol %. The phosphors are produced by mixing the corresponding oxides with an excess of ammonium bromide and subsequently firing at 400 – 500 °C. The reaction product is then subjected to crystallization firing with an alkali-metal bromide at 600 – 1100 °C [148]. The oxybromides are also formed by firing the oxides in a hydrogen bromide atmosphere. By coactivation, with ytterbium, the afterglow, which causes problems in medical applications, can be reduced. Partial substitution of lanthanum by gadolinium in $LaOBr:Ce^{3+}$ leads to an increase in the quantum yield upon electron excitation and an increase in the quenching temperature [149].

Table 2. Manganese-activated halide phosphors

Composition	WTDS Specification	Color location		Decay
		x	y	
$(Zn, Mg)F_2:Mn^{2+}$	LB	0.557	0.442	long
$KMg\ F_3:Mn^{2+}$	LC	0.573	0.426	very long
$MgF_2:Mn^{2+}$	LD	0.559	0.440	very long
$(Zn, Mg)F_2:Mn^{2+}$	LK	0.591	0.407	very long

1.4. Uses of Luminescent Pigments

1.4.1. Lighting

For a detailed description of the lamps discussed in this Section, see → Lamps.

Most inorganic phosphors are used in mercury vapor lamps. In these light sources, a plasma is produced from an inert gas and mercury vapor by electrical discharge. The plasma emits intense UV radiation, whose wavelength depends on the vapor pressure. The conversion of the UV radiation into visible light is effected by phosphors applied as a thin coating on the inside of the glass of the lamp. The numerous phosphors with various emission colors in industrial use make it possible to produce practically any desired light color or wavelength in the spectrum by means of the UV radiation from the gas discharge. Depending on the mode of operation of the gas discharge, there are two types of mercury discharge: low pressure and high pressure. The phosphor has a different function in the two types of discharge.

Fluorescent Lamps (Low-Pressure Mercury Lamps). In fluorescent lamps the phosphor is excited by energy-rich mercury resonance lines at 254 and 185 nm. For many years the most important phosphors were the halophosphates. Not only were fluorescent lamps for white light colors produced with these, but the so-called color-improved Deluxe Lamps were produced by means of mixtures with red phosphors. However, the maintenance of these halophosphate phosphors is not good. The quantum yield decreases by almost a third due to the radiation-induced decomposition of the halophosphate phosphor even after only 10 000 h of use. By lowering the diameter of the fluorescent tube from 38 to 26 mm, the specific radiation loading is also increased. In the search for more efficient phosphors with greater radiation-stability, blends of $Y_2O_3:Eu^{3+}$, $Ce_{0.65}Tb_{0.35}MgAl_{11}O_{19}$, and $BaMg_2Al_{16}O_{27}:Eu^{2+}$ were used from the 1970 s. With these trichromatic blends the quantum yield could not only be considerably improved but the color rendition of the fluorescent lamps became comparable to those of the earlier Deluxe fluorescent lamps because of the high proportion of red radiation.

High-Pressure Mercury Lamps. Phosphors for high-pressure mercury vapor lamps have to fill up the red part of the spectrum of these lamps, which otherwise emit intense radiation in the blue and green regions.

The lamp can reach an operating temperature of 150 – 300 °C, depending on the power rating. The phosphors must therefore have a very high quenching temperature. In addition they must be readily excitable in the long-wavelength UV. Many phosphors do not meet these criteria for use in high-pressure lamps. 3.5 $MgO{\cdot}0.5\ MgF_2{\cdot}GeO_2:Mn^{4+}$ and $YVO_4:Eu^{3+}$ have proved to be suitable. The excitation spectrum shifts towards longer wavelengths with increasing temperature for $YVO_4:Eu^{3+}$ and the quenching temperature is high. The magnesium fluorogermanate radiates in the deep red region; however, itis not as temperature stable as the vanadate.

UV Lamps. Special applications of UV phosphors include fluorescent lamps for tanning (sun studios), photocopier lamps, and lamps for photochemistry, medicine, and varnish harden-ing. Phosphors which are suitable here are $Ce(Mg,Ba)Al_{11}O_{19}$ ($\lambda_{max.} = 344$ nm), $BaSi_2O_5:Pb^{2+}$ (351 nm), $2\,SrO{\cdot}6\,B_2O_3{\cdot}SrF_2:Eu^{2+}$ (371 nm), $(Sr, Mg)_2P_2O_7:Eu^{2+}$ (392 nm), and $(Ba, Zn, Mg)_3Si_2O_7:Pb^{2+}$ (303 nm).

High-Voltage Advertisement Illumination Tubes. High voltage tubes with cold cathodes are widely distributed in illuminated advertisements in the form of letters, title strips, illuminated motifs, for lighting effects at exhibitions and show windows, and for façade illumination of department stores. The light colors of such tubes can be adjusted by colored glass, the filling gas (neon gives red; helium, white-pink; argon–mercury, blue), and varied precisely by the phosphors (Table 3, see next page) [150, 151].

1.4.2. X-ray Technology

By means of phosphors, the invisible shadow image which is formed on penetration of an object by X-rays is converted into a visible image which can then be examined. The phosphors

Figure 10. a) Sensitivity of human eye (night); b) Emission spectrum of (Zn, Cd)S:Ag fluoroscopic screen; c) Sensitivity of human eye (day)

must have a high effective quantum absorption for the energy-rich X-rays (20 – 60 keV). Thus, compounds of elements with high atomic numbers are principally used. The emission spectrum should correspond to the spectral sensitivity of the detector as well as possible. In the particle size distribution, a compromise between high brightness (coarse particles) and good image-transfer properties (fine particles) must be sought. The afterglow should be so low that on taking pictures of moving parts the image is not blurred. Different quality requirements exist for the various X-ray techniques. Therefore phosphors are used which are adapted to suit the particular application.

Fluoroscopic screens allow direct examination of X-ray images by the eye. Today a (Zn, Cd) S:Ag is used almost exclusively in which the molar ratio of ZnS:CdS is 60:40. The particle size lies between 20 and 40 µm. The emission spectrum corresponds well to the spectral sensitivity of the eye (Fig. 10).

The fluoroscopic screen consists of a substrate (cardboard, plastic sheet), which is first covered with a reflective layer of MgO or TiO_2. The phosphor layer is applied by pouring, after dispersion in a binding agent based on acetylcellulose. The density of the phosphor coating is 70 – 140 mg/cm^2. Gd_2O_2S:Tb is also used for the conversion of energy-rich X-rays (80 keV), for example, in luggage checking machines.

Intensifying Screens. Since X-ray films can only use 1 % of the incident X-rays for nucleation because of their low absorption, intensifying screens for X-ray photons are used in medical diagnosis for taking X-ray photographs. Here the X-rays are first converted into light which then irradiates the film. In most cases, two intensifying screens are used, the phosphor screen placed in front of the film (front screen) very often having a thinner coating than the rear screen.

Until recently, luminescent pigments with blue emission in combination with blue-sensitive films were used exclusively. Since the introduction of green-sensitive film material into X-ray technology, green-emitting phosphors are now being increasingly used. The most important phosphors are listed in Table 4.

Intensifying screens consist of cardboard or plastic sheets (e.g., polyester) as substrates. A reflective layer (e.g., TiO_2) is first applied to this and then the phosphor-binder layer. Gelatine, nitrocellulose, or polymethylmethacrylate are, for example, used as binders. The density of the phosphor coating is 10 – 100 mg/cm^2.

Storage panels (Fig. 11) are, in principle, constructed like intensifying screens. However, they differ in that a phosphor is used that, on excitation with X-rays, stores part of the absorbed energy in addition to producing spontaneous emission. The stored energy can later be read out by stimulation with light of a suitable wavelength, for example, with a finely focused laser beam. The possibility thus exists for computer digital radiography, in which information stored simultaneously (in parallel) is then read out serially [153]. Objects with large differences in contrast can be represented without loss with this technique.

Table 4. Phosphors for intensifying screens [124, 152].

X-ray phosphor	Absorption at 80 kV, %	Conversion into light, %	Density, g/cm^3	Emission maximum, nm
$CaWO_4$	26.7	4	6.8	425
$Y_2O_2S:Tb^{3+}$	27.0	18	5.0	418, 545
$Gd_2O_2S:Tb^{3+}$	37.7	15	7.44	545
$BaFCl:Eu^{2+}$	39.7	12	4.56	385
$LaOBr:Tb^{3+}$	41.5	13	6.28	437

$Y_2O_2S:Eu^{3+}$, Bi^{3+} ; $GdOBr:Sm^{3+}$; $LaOBr:Tb^{3+}$, Bi^{3+} ; and the barium fluorohalides are among the known storage phosphors. At present, $BaFBr:Eu^{2+}$ with various coactivators, mostly transition metals, is principally used in industry.

X-Ray Image Intensifiers. The use of an optoelectronic image intensifier is more efficient than direct examination with a fluoroscopic screen [154]. Further development of this principle led to the optoelectronic X-ray image intensifier (Fig. 12), [155], in which the X-ray phosphor screen (input screen) is in direct optical contact with a photocathode that converts the luminance distribution of the X-ray screen into an electron-density distribution. The electrons liberated are accelerated in an electric field between the photocathode and an anode (20 – 30 kV) and are focused by electron lenses onto a further phosphor screen (output screen), where conversion of the electron image to a visible image takes place. The two phosphor screens in the X-ray image intensifier differ in their construction, corresponding to their differing functions.

Figure 12. X-ray image intensifier
a) Glass envelope; b) Input conversion screen; c) Photocathode; d) Focusing electrodes; e) Anode; f) Output screen

Formerly, $(Zn, Cd)S:Ag^+$ was used for the *input screen* of these X-ray image intensifiers. This phosphor was sedimented onto the base material of the input screen (glass or metal sheet) from a suspension. Since ca. 1970, the input screens have mostly been made by condensing $CsI:Na^+$ onto thin aluminum sheets in vacuum. Cesium iodide has a higher mass extinction coefficient than (Zn, Cd)S. The evaporation coating process also gives a considerably higher packing density, which leads to higher resolution at coating densities of up to 120 mg/cm^2. The emission spectrum of $CsI:Na^+$ corresponds well with the sensitivity of the Cs_3Sb photocathode.

The *output screen* consists of a glass base material (sometimes also fiber optics), onto which fine particles of $(Zn, Cd)S:Ag^+$ are applied, usu-

ally by sedimentation, but also by brushing or spraying. Because of the optoelectronic diminution of the image (10:1 to 15:1) onto the relatively small output screen (20 – 40 mm diameter), the phosphor layer must have high resolution. Phosphors with an average particle size of 1.5 – 3 µm and a narrow particle size distribution are used. The thickness of the layer is ca. 5 – 10 µm, which corresponds to a coating density of 0.8 –1.6 mg/cm^2 of $(Zn, Cd)S:Ag^+$.

Computer Tomography. In computer tomography the patient to be examined lies within a circle of detectors (up to 1200) [156]. A con-

tinually irradiating X-ray tube rotates around the patient. The detectors measure the intensity of the X-rays which have passed through a particular layer of the body in each direction.

The detectors consist of a phosphor crystal which is combined with a photodiode. The electrical signals of the individual detectors are combined by computer to form an image.

In modern instruments, single crystals of $CdWO_4$ and $Bi_4Ge_3O_{12}$ ($\lambda_{max} = 480$ nm) are used, which achieve an absorption of up to 98 % in the short length required by the construction and have a high quantum yield. A fast decay is important for achieving a high signal-to-noise ratio [157].

1.4.3. Cathode-Ray Tubes

Phosphors are an important, quality-determining component of cathode-ray tubes (Fig. 13). In the phosphor screen, modulated electrons are converted into a visible image. Many methods exist for the production of phosphor screens [7]. Monochromatic tubes are predominantly produced by the sedimentation (settling) process. A suspension of the phosphor in alcohol or water, with addition of water glass solution, is placed in the tube and is deposited by sedimentation on the inner surface of the faceplate. There it forms a regular layer whose adhesion, both to itself and to the glass, is effected by the slowly precipitating silicic acid. The coagulation time of the water glass is adapted to the sedimentation rate of the phosphor by addition of electrolytes.

Figure 13. Schematic of a cathode-ray tube
a) Electron guns; b) Optoelectronic system; c) Shadow mask; d) Phosphor screen

The coating of color picture tubes is carried out in such a way that the three components red, green, and blue are applied consecutively as dispersions in a photosensitive resin. This is then exposed via a shadow mask so that the resin on the exposed areas becomes water-insoluble. The phosphor on the unexposed areas is then washed off with water.

For special tubes, other methods, such as electrophoresis or brushing, are also sometimes used. In most cases the phosphor layer is then subjected to an aluminum vapor deposition process. This causes an increase in the brightness by reflection of the backward-radiating luminescence and inhibits charge build-up in the phosphor layer.

Cathode-ray tubes have a very large number of applications which require varying phosphor qualities. Table 5 (see previous page) lists the most important cathode-ray luminescent pigments.

Since April 1982 the Worldwide Phosphor Type Designation System (WTDS) has existed, in which the optical data of the various phosphors for cathode-ray tubes are laid down [158]. It replaces several phosphor designation systems (e.g., TEPAC, Pro Electron) previously in use in various countries. As well as the chemical composition, WTDS records the fluorescence spectrum, the phosphorescence spectrum under the various usual operating conditions, the color coordinates x and y in the standard coordinate chromaticity diagram of the International Commission on Illumination [ICI or CIE (Commision International de l'Eclairage) system, 1931] [159], and the decay time. The phosphors are characterized by two capital letters, the first giving the position of the emission color in the Kelly Charts of Color Designation:

A: purple-red, purple, violet,
B: blue, greenish blue,
G: blue-green, green, yellow-green,
K: yellow-green
L: orange, yellow-orange,
R: red-orange, red, purple-red, pink, purple-pink,
W: white,
Y: green-yellow, yellow, orange-yellow.

The second letter is assigned to a particular product.

Television and Monitor Tubes. The main requirements for phosphors in television tubes

(Table 5) concern brightness, decay time, and color. While the brightness should generally be as high as possible, the decay time must be adapted to the image frequency to decrease flicker and poor image definition. The white luminescence required for black and white televisions is achieved with blends of $ZnS:Ag^+$ and $(Zn, Cd)S:Cu^+$, which give complementary blue and yellow emission. One-component phosphors which emit white light due to double activation have not been successful [59, 60].

In color picture tubes, the final color is formed by additive mixing of red, green, and blue light. Each of the three phosphors is excited by its own modulated electron beam and emits light of intensity corresponding to the particular degree of excitation. $(Zn, Cd)S:Ag^+$ and $(Zn, Cd)S:Cu^+$, Al^{3+} are used as the green-emitting component. Because of the toxicity of cadmium, however, they are now being replaced by $ZnS:Cu^+$, Al^{3+} and $ZnS:Cu^+$, Au^+, Al^{3+}. The phosphor $ZnS:Ag^+$ is exclusively used as the blue component. The most important red component is $Y_2O_2S:Eu^{3+}$ with a Eu concentration of 3 mol %; $Y_2O_3:Eu^{3+}$ is now less widely used for this purpose. The phosphors for color picture tubes have an average particle size of 8 –10 µm.

The requirements of phosphors for monitor tubes differ from those for entertainment tubes. Because of the high resolution required for monitor tubes, phosphors with smaller particle sizes are often needed. They are between 6 and 4 µm, for special applications even lower. For monitor tubes which reproduce slow movement only, phosphors with longer decay times are used to diminish image flickering. In $ZnS:Cu^+ + Zn_2SiO_4:Mn^{2+}$, As^{3+} and $(Ca, Mg)SiO_3: Ce^{3+} + (Zn, Mg)F_2:Mn^{2+}$, the decay times of the blends are prolonged by the second component (see Table 5). For the reproduction of faster movement, phosphors with shorter decay times are used, for example, $Y_2Si_2O_5:Ce^{3+}$, Tb^{3+} (white). For monochrome monitors with amber as the image color $Cd_5(PO_4)_3Cl:Mn^{2+}$ or a blend of $Y_2O_2S:Eu^{3+}$ and $(Zn, Cd)S:Cu^+$ is used.

The majority of phosphors for cathode-ray tubes are coated with an oxide, silicate, or phosphate before use to improve their processing properties and stability to burn-in. Pigmenting of $Y_2O_2S:Eu^{3+}$ with finely-divided Fe_2O_3 and of $ZnS:Ag^+$ with ultramarine or cobalt aluminate is also known. The incorporated pigment, which has the same body-color as the emission color of the phosphor, absorbs incident ambient light, effecting an increase in contrast [160].

A special case of pigmenting is the coating of one phosphor with another. This type of phosphor (onion-skin) is used in so-called penetration tubes. At lower acceleration voltages the luminescence of the outer phosphor dominates, and at higher voltages, that of the inner phosphor. In addition, phosphor blends are used, the components of which exhibit differing brightness–voltage dependencies. By using phosphors with differing decay times or emission colors, monitor tubes with differing afterglow times (variable persistence penetration CRT) or colors (multicolor penetration CRT) can be realized. Compared to three-electron-beam tubes, penetration tubes stand out because of their higher resolution and lower susceptibility to interference.

Oscilloscopes are electrical measuring instruments for the display and monitoring of rapidly changing electrical processes, for example, changes in voltage and current with time. An important part of these instruments is the display tube (Fig. 14). In this cathode-ray tube, a thermionic cathode emits an electron beam which is directed by the modulator and passes through two pairs of deflector plates placed at right angles to each other and then excites a phosphor screen. The operating voltage is 1 –15 kV. Because the energy of the electrons is low, phosphor screens without aluminum backing can also be used. The luminescent pigments are listed in Table 5. They must have a good efficiency for the particular electron energy. For tubes for the detection of fast processes, a short decay time is necessary. On the other hand, for the display of slow or periodic processes with low frequencies, phosphors with very long afterglows are used. The choice of emission color depends on the spectral sensitivity of the particular detector. For visual examination, green-emitting products are used, and for photographic examination, blue-emitting ones. The phosphor screens are mostly produced by sedimentation with water glass as the binding agent. A centrifugal process and cataphoresis are also used. For an operating voltage of 1 – 10 kV, a coating density of 2 – 8 mg/cm^2 is used.

Figure 14. Oscilloscope tube
a) Cathode; b) Modulator; c) Electron lens; d) Y-plates; e) X-plates; f) Electron beam; g) Phosphor screen

Radar Tubes. In construction, a radar tube corresponds to the oscilloscope tube. It displays radar echos, i.e., the direction of and the transit time to and from a reflecting object.

Since the pulse duration is of the order of microseconds, the response time of the phosphor must be correspondingly short. On the other hand, the afterglow of the screen should be long enough for the radar image to be regenerated after one rotation of the radar antenna (of the order of seconds). These requirements are achieved by means of a combination of phosphors. In the *cascade screen*, two superimposed phosphor layers are used. The first consists of a blue, cathodoluminescent, fast-responding phosphor. The blue light of this phosphor excites the photoluminescent phosphor with yellow afterglow in the second layer; $ZnS:Ag^+$ (blue) and $(Zn, Cd)S:Cu^+$ (yellow) are an example of such a cascade. For the observation of moving objects, an even longer afterglow (of the order of minutes) is often desirable to obtain an impression of the direction and speed of the object from the direction and length of the afterglow trace. Suitable phosphors are listed in Table 5.

In *penetration tubes*, two phosphor layers, separated by a barrier layer, are applied to the phosphor screen. At lower acceleration voltages, only the first phosphor is excited and luminesces with its characteristic color and afterglow time. At higher voltages both phosphors luminesce. Since most electrons are then absorbed in the second layer, this determines the color and afterglow time. It is thus possible with only one electron beam to display simultaneously the inscription in one color with short afterglow and the radar signal in another with long afterglow by changing the voltage, as can be seen in the case of the phosphor VE in Table 5.

Flying-Spot Tubes. A rapidly moving spot of light (flying spot), obtained by focusing an electron beam onto the phosphor screen of a cathode-ray tube scans a photo or a film. The light which passes through or is reflected is then converted into signals in a photodiode behind or in front of the object, respectively. A short decay time (< 100 ns) and high spot brightness are important for fast scanning. In monochrome scanning tubes, the ZnO:Zn used initially has been replaced by $(Zn, Cd)S:Ag^+, Ni^{2+}$. In color scanning, blends of $Y_3Al_5O_{12}:Ce^{3+}$ with $Ca_2Al_2SiO_7:Ce^{3+}$ or $SrGa_2S_4:Ce^{3+}$ with $SrGa_2S_4:Pb^{2+}$ can be employed.

Optoelectronic Image Converter. The image converter is an optoelectronic system which converts an image invisible to the human eye first into an electron image and the latter into a visible one [161]. The image converter extends human vision into UV, IR, and X-ray regions. Figure 15 shows the principle of the converter. Light emitted from an object releases electrons in the photocathode in proportion to its intensity. The electrons are accelerated in the electron-optical system and focused onto a phosphor screen. Here the electron image is converted to an image that can be examined with the eye or further processed by means of other detectors such as film or television cameras.

Figure 15. Optoelectronic image converter and intensifier, principle
a) Object; b) Imaging objective; c) Optical image; d) Optoelectronic imaging system; e) Electron image; f) Detector (eye or film); g) Phosphor screen; h) Photocathode

The quality of the system is determined to a great extent by the phosphor screen and the phosphor used. The phosphor should have as high a quantum yield as possible on excitation with 6 – 20 keV electrons and must be resistant to the alkali-metal vapors present during the production of the photocathode and to ion bombardment. The emission spectrum should be adapted to the spectral sensitivity of the particular detector. The requirements for high resolution and

Table 6. Phosphors for image converters

Phosphor	Typical particle-size distribution, µm			Emission peak, nm
	5 %≤	50 %≤	95 %≤	
(Zn, Cd)S:Ag^+	1.3	2.3	3.8	532
ZnS:Cu^+	1.3	2.5	5.0	525
Zn_2SiO_4:Mn^{2+}	1.5	3.5	9.0	526
Gd_2O_2S:Tb^{3+}	2.0	3.5	9.0	547
ZnS:Ag^+	1.1	2.5	6.0	446
CdS:Cu^+	2.6	9.4	21.0	845

good contrast lead to particular requirements for the particle size and particle-size distribution of the phosphor. The average particle size should not exceed 4 µm. The decay time should correspond to the classification medium to medium short. For special applications, luminescent pigments with the classification short and very short are required. Some important phosphors for image converters are listed in Table 6.

1.4.4. Product Coding

Phosphors are used extensively for coding of mass-produced goods or high value trademarked articles. For mass-produced goods, they serve to distinguish between particular types or, at a later stage, for the control of production batches. In the case of trade marked articles, coding with phosphors allows rapid recognition of imitations in the fight against product piracy. The phosphor is applied by means of transparent or colorless printing inks in the form of bar codes, numbers, or company emblems. Fluorescent fibers for packaging paper or fluorescent stick-on labels are further forms of coding. Phosphors are preferred that have clearly defined and narrow-banded emission, particularly under longwavelength UV light. Phosphors based on zinc sulfide, zinc cadmium sulfide, and various rare-earth compounds with white body color are usually used.

The readily excitable fluorescence or phosphorescence of phosphors can also be made use of in the automation, control, and regulation of automatic sorting processes, e.g., for mass-produced goods, in packaging or in quality control.

Since the 1960 s, stamp paper has been treated with fluorescent or phosphorescent phosphors. Since the stamp is stuck to the top right-hand corner of the letter, its recognition by the machine serves to establish the position of the letter and enables machine control of the correct positioning for postmarking and reading. The advantage of the phosphorescence of many inorganic phosphors lies in the fact that excitation and photoelectric scanning can be carried out separately. Thus the interfering blue emission of the optical brighteners present in most papers can be eliminated. By using fluorescing phosphors the blue emission of optical brighteners can be eliminated by inserting a blue filter (< 500 nm) with a sharp absorption edge. Fluorescent phosphors in stamps are preferably organic, while doped zinc sulfides with average particle sizes of 5 – 6 µm are used as afterglow phosphors.

The phosphor is either added to the paper pulp or applied as a surface coating of 1 – 2 g/m^2, which gives a readily detectable signal strength. Printing of fluorescent or afterglowing bar codes which allow, for example, sorting according to type of transport is increasing.

Some photoelectric scanning instruments combine excitation and photoelectric recognition into one system (luminescence scanners).

The coding of checks and check cards, passports, personal identity cards, securities, gift vouchers, entrance tickets, season tickets, and banknotes, with phosphors as invisible security markings is widely used. By this type of coding the phosphor acts as a passive protection against forgery and copying. With modern color copiers it is possible to produce forgeries which are virtually impossible for non-specialists to differentiate from the original. Using phosphors this differentiation is very simple. The original, with phosphor, fluoresces under UV light, the copy does not. Phosphors with white body color are generally used. The incorporation into the original is generally carried out by means of pulp coloration, embedding in plastic articles or us-

ing various printing processes, of which screen-printing is the most important because of the relatively coarse-grained nature of inorganic phosphors.

1.4.5. Safety and Accident Prevention

Inorganic luminescent pigments with long afterglows have long been used to make danger areas, escape routes, and switches visible.

For this application, phosphors must have the following properties:

1) excitability by daylight and artificial light,
2) high luminance during the first hour after excitation,
3) long afterglow time, i.e., decrease in luminance to 100 times that still detectable by the human eye (ca. 0.3 mcd/m^2) only after several hours,
4) an emission spectrum corresponding to the sensitivity curve of the eye, and
5) high chemical stability.

Zinc sulfide, zinc – cadmium sulfide and, with certain limitations, alkaline-earth sulfides form the basis of these phosphors. Table 7 lists commercial industrial phosphors. Copper-activated zinc sulfides are the most widely used phosphors for safety purposes. Their spectra correspond well with the sensitivity of the eye and it is excited by daylight and artificial light. At an illuminance of over 700 lx, complete excitation takes place within 30 s.

These zinc sulfides are sufficiently resistant to all media except strong mineral acids. A disadvantage is that they become grey through the action of high intensity UV light in the presence of water, due to photochemical reduction of Zn^{2+} to Zn^0. This effect can be reduced by coating with a UV-absorbing layer, but the outdoor application of these phosphors is limited. The phosphors are used in afterglow paints, plastics, ceramics and enamels.

The following basic rules should be observed in processing luminescent pigments:

1) The binder system must be colorless and transparent.
2) Additives based on heavy metals should not be used. This is particularly important at high processing temperatures.

Table 7. Properties of industrially important long-afterglow phosphors for accident prevention

Designation and luminescent color	Composition	Body color	Average particle size (FSSS)	Sieve analysis mesh size, µm	Sieve analysis residue, wt %	Typical luminance, mcd/m^2 3 min	10 min	30 min	60 min	100-fold visibility limit 0.32 mcd/m^2 in min.

3) Processes involving the action of large shearing forces on the pigments should be avoided (pressure-induced deterioration of luminescent pigments).

Markings for switches and escape routes, advice and warning signs, and special protective work clothes are produced increasingly from these afterglow phosphors.

In contrast to normal emergency illuminations, which are invisible or poorly visible in the presence of smoke, a low-light escape route system based on afterglowing pigments remains noticeable even in smoke [162–164]. The construction and action of such a system is shown in Figure 16.

Figure 16. Low light level escape route system based on afterglowing LUMILUX$^{(R)}$ Green N phosphor

Guidelines for the measurement and characterization of long-afterglow products and systems are given in DIN 67 510.

1.4.6. Dentistry

Natural teeth exhibit blue-white fluorescence with a characteristic spectral distribution through the action of long-wavelength UV light [165]. The luminescence is attributed to certain components of collagen [166, 167].

For cosmetic reasons, the imitation of this phenomenon has long been attempted in the production of artificial teeth. Initially, uranyl salts were added to the ceramic paste. However, this also produced radioactivity in the artificial teeth [168]. Therefore, this technique has been abandoned, and the production of a fluorescence corresponding to that of natural teeth was attempted by the addition of rare earths or other activators [169]. The endeavors failed because the heat treatment necessary in the processing of the ceramics leads to uncontrolled changes in the intensity and spectrum of the emission. Later, luminescent pigments were developed which could be processed in the ceramic paste and gave the artificial teeth made from it blue-white fluorescence in the long-wavelength UV.

Yttrium silicates doped with cerium, terbium, and manganese give the best results [170]. A typical composition is $(Y_{0.937}Ce_{0.021}Tb_{0.033}Mn_{0.009})_2SiO_5$. The excitation maximum of these phosphors is in the range 325 – 370 nm (Fig. 17).

Figure 17. Excitation spectra of pigments for dental application
a) LUMILUX blue-white Z; b) LUMILUX yellow-white Z

The fluorescence color of the teeth can be varied by changing the concentration of activators in the phosphor, as the spectra of two commercial products show (Fig. 18). Addition of 0.3–0.5 wt % to the ceramic paste gives the artificial teeth the same fluorescence as natural teeth under the action of UV.

Figure 18. Emission spectra of pigments for dental application
a) LUMILUX blue-white; b) LUMILUX yellow-white

1.4.7. Other Uses

Green-fluorescing Zn_2SiO_4:Mn^{2+} and magnesium tungstate that fluoresces blue under short-wavelength UV are mixed with the sorbents (silica gel, aluminum oxide) of *TLC plates* in proportions of ca. 3 wt % to improve the contrast in the detection of UV-absorbing compounds. For this application the phosphors must be particularly fine grained and must not alter the pH value of the sorbent.

Infrared radiation can be detected by phosphors by various mechanisms. Upon excitation with UV radiation, ZnS:Cu^+, Co^{2+} emits an afterglow that is quenched by IR radiation, whereas ZnS:Cu^+, Pb^{2+} stores excitation energy and emits it spontaneously under the action of IR radiation.

The phosphors CaS:Sm^{3+}, Ce^{3+} and SrS:Sm^{3+}, Eu^{2+} only exhibit low fluorescence on excitation by UV radiation and daylight. Through the subsequent action of IR radiation these phosphors can be stimulated to emit green or orange-red light.

Infrared-stimulable phosphors are used as screens for the detection of IR radiation in IR measuring and testing techniques and for the adjustment of IR lasers, and IR light recorders. This method is cheaper than IR display devices.

Scintillation counters are used to detect energy-rich particles and γ-rays. They consist of a combination of a phosphor, usually a single crystal, with a photomultiplier or a photodiode as detector. When energy-rich particles impinge on the phosphor crystal, a flash of light is formed which is registered by the detector. It is important for the phosphors to have a high absorption for the exciting energy and a short decay time ($< 1\ \mu$s), to produce high counting rates at a good signal-to-noise ratio and proportionality between the absorbed energy and the number of photons emitted. Alkali-metal iodides (see Table 1), $Bi_4Ge_3O_{12}$, $CaWO_4$, $ZnWO_4$, $CdWO_4$, and ZnS:Ag^+, Ni^+ are typical phosphors for this application [170].

Thermoluminescence dosimeters (TLD) absorb ionizing radiation and accumulate the energy absorbed over a very long period. Heating the TLD results in emission of light proportional to the absorbed energy. For monitoring a person, an effective atomic number of the TLD is chosen to be as near as possible to that of human tissue; $Li_2B_4O_7$:Mn^{2+}, LiF (see Table 1), and also $CaSO_4$:Dy^{3+} and CaF_2:Mn^{2+} meet this requirement. For use as a TLD, the phosphor is encapsulated in a glass ampoule or is sealed in a heat-resistant synthetic resin.

Phosphors for radio-activation are used as mixtures with a radioactive compound whose radiation effects continuous luminescence of the phosphor. The radium compound used formerly in the production of radio-activated systems restricted their lifetime in spite of the very high luminescence yield and long half-life, because the exciting α-particles of the radium decompose the phosphor [171]. After the radiation safety regulations for α-emitters became stricter, β-emitters were used instead, even though the luminescence yield is less efficient for a given activity. Compounds with high β-activity were therefore used such as ^{3}H, ^{14}C, or ^{147}Pm compounds. In addition, β-radiation has the advantage that it causes less decomposition of the phosphor.

Tritium-labeled organic binders are used for the production of luminous products and paints. Because of the high cost of tritium, the phosphors must have a high efficiency.

Another radioactive luminescent system is the β-light, which consists of a gas-tight glass vessel that contains gaseous tritium and whose walls are coated with a fine-grained phosphor. The β-lights are mainly used in military applications for the illumination of instruments and scales. Clock faces and hands, escape route signs, and emergency exits are also made visible in darkness through the use of β-lights.

Because of health risks, particularly through the use of radioactive substances, their use is declining sharply and they are being replaced by long-afterglow products.

Fluorescent and afterglow products are used to attain particular effects in cinema films, on the stage and in works of art. These *effect pigments* are physiologically harmless phosphors, mainly based on zinc sulfides.

1.5. Testing of Industrial Phosphors

Luminescence color is determined by visual comparison, by calculation of the color coordinates x and y from the emission spectrum, or by means of a tri-stimulus colorimeter under the excitation definitive for the application (UV radiation, cathode rays, etc.).

Luminescence Brightness. A practical brightness measurement for UV-excitable phosphors is the comparison with internal reference phos-phors under excitation mainly with short- and long-wavelength (254 nm and 365 nm) UV lamps. The visible parts of the radiation from the mercury discharge must be removed with filters. Integral brightness values in mcd/m^2 are obtained with commercial brightness measuring instruments.

Values of the quantum yield are obtained by comparison measurements against standard phosphors of the NBS. The dependence of the quantum output on the excitation wavelength are obtained by comparison with phosphors whose quantum output is only slightly dependent on the excitation wavelength. Such phosphors are, for the blue emission region, sodium salicylate, for the blue-green, coronene ($C_{24}H_{12}$), and for the orange to orange-red, Lumogen Red T (BASF). Measurements of quantum yield are rarely carried out on industrial phosphors. The absolute measurement of the quantum yields is described in detail in [129, 172].

For long-afterglow phosphors, the brightness as a function of time after standardized excitation is measured. The excitation and measurement of the brightness decay and the characterization of products with long afterglow phosphors is laid down in DIN 67 510.

Phosphors for cathode-ray tubes, television screens, monitor screens, radar screens, and oscilloscopes are tested under electron excitation. Electron energy and density should be similar to the conditions of the tube in which the screen will be used. The phosphors are sedimented or brushed onto light-permeable screens and coated with an evaporated aluminum coating to dissipate charge. The luminescence brightness and color of the emitted light are measured with optical instruments such as photomultipliers or spectrophotometers.

For X-ray excitable phosphors, the intensifier effect is tested as a measure of the luminescence yield. A very simple process uses the exposure of blue- or green-sensitive films. The phosphor is excited by X-rays in a cell covered with a light-sensitive film. The blackening of the film is measured with a densitometer and, for given excitation conditions, is a measure of the efficiency of the phosphor.

Particle Size and Shape. The measurement of particle-size distribution is carried out with particle counting instruments (Coulter counter) or by laser or light-beam scattering (Cilas). The Fisher number is still widely used as a measure of the average particle diameter (Fisher sub sieve size). The average particle diameter is measured by means of the air permeability principle [173, 174].

The form and composition of phosphor crystals are assessed by scanning electron microscopy. Halophosphate phosphors have a lamellar form and $CaWO_4$ crystals are, for example, spherical.

For relatively coarse phosphors, such as $ZnS:Cu^+$, the particle-size distribution is determined from sieve residue curves.

Decay. The decay time requirements must be adhered to very precisely for cathode-ray tube phosphors. The measuring devices consist of fast excitation sources (flash lamps, lasers), photo-

multipliers with very low time constants, and an oscilloscope [171].

Sedimentation Behavior. The coating of cathode-ray tubes is usually carried out by sedimentation. The sedimentation rate in the sedimentation fluid is principally determined according to Stokes' law by the size, shape, density, and surface charge of the particles. The sedimentation characteristics of CRT phosphors and their blends under typical application conditions is an important criterion for their suitability, apart from the luminescence brightness and luminescence color.

The sedimentation density allows conclusions to be made on the degree of agglomeration of individual crystals at constant polarity and electrolyte concentration of the sedimentation fluid. A low density is an indication of extensive agglomerate formation.

Conductivity and pH of the Aqueous Extract. The conductivity and pH value of aqueous phosphor slurries are indications of hydrolysis processes, poor washing out of the flux from the phosphor, or the presence of acidic or alkaline coatings. Increases in the conductivity of the slurry caused by electrolytes is often a disadvantage in the production of image screens by means of the sedimentation process.

For phosphors that are applied by cataphoresis, the zeta potential is occasionally tested. In some cases, the specific surface area (BET) is also used for assessment.

For lamp phosphors, the definitive quality report is only given after tests in lamps, for which the most important criterion is the quantum yield throughout the lifetime.

2. Chemiluminescence and Bioluminescence

2.1. Introduction

Chemiluminescence is the emission of light from a chemical reaction. The energetics of this process are shown in Figure 19, which also gives for comparison the energy diagrams of typical nonluminescent thermal and photochemical reactions. For the nonluminescent thermal reaction (Fig. 19 A), the ground state reactant R_0 is activated by thermal energy to the transition state $R\neq$, which, after reorganization of the chemical bonds, affords the ground state product P_0; excess energy is dissipated as heat. This represents by far the most common chemical transformation.

In a photochemical process (Fig. 19 B), R_0 is promoted by absorption of light energy to the electronically excited reactant $R*$, which on reorganization of the chemical bonds leads to P_0, and excess energy is liberated as heat.

Although the chemiluminescent reaction (Fig. 19 C) has characteristics of both, it is unique and distinct in that thermal activation of R_0 leads to $R\neq$, which upon bond reorganization generates an electronically excited product $P*$, the latter affording P_0 with light emission.

Figure 19. Energy level diagrams for typical chemical reactions
A) a thermal exothermic process; B) photochemical transformation; C) a chemiluminescent process

Bioluminescence is identical to chemiluminescence, except that light is emitted by biological matter, e.g., bacteria, fungi, plants, insects, and fish. A chemical reaction, promoted by enzymes, takes place in the living cell, generating an electronically excited product P∗, which manifests itself through characteristic light emission. A well-known example is the firefly.

Phenomena related to chemiluminescence and bioluminescence include anodoluminescence, candoluminescence, cathodoluminescence, electrochemiluminescence, piezoluminescence, pyroluminescence, radioluminescence, sonoluminescence, thermoluminescence, and triboluminescence.

2.2. History

Bioluminescence has been much longer known to humans than chemiluminescence. The Chinese reported the emission of "living light" ca. 5000 years ago. The first experimental inquires are credited to Aristotle, who recognized the heatless nature of bioluminescence over 2000 years ago. Scientific investigations of bioluminescence commenced with BOYLE, who demonstrated the requirement for oxygen in the emission exhibited by fungi associated with decaying plant matter (fox fire). NEWTON, FRAN-KLIN, DUBOIS, and others contributed decisively in the following period to the understanding of bioluminescence; but it was HARVEY [175] who developed the biochemical basis of modern research in this field. Contemporary research is summarized in [176, 177].

The history of chemiluminescence is much younger [178]. The first report of chemiluminescence in solution–the autoxidation of lophine (**1**)–was made by RADZISZEWSKI in 1871.

1

The earliest mention of singlet oxygen chemiluminescence dates to BLANCHETIERRE (1913), who observed a bright red emission when chlorine gas was passed through an alkaline hydrogen peroxide solution. DUFRAISSE (1926) is credited with the discovery of the singlet-oxygen chemiluminescence observed in the thermal decomposition of rubrene endoperoxide (**2**).

2

The autoxidation of luminol (**3**), leading to the emission of bluish light, was discovered by ALBRECHT (1928).

3

The perhydrolysis (reaction with H_2O_2) of lucigenin (**4**) was observed by GLEN and PLETSCH (1935), while that of oxalyl chloride was first reported by CHANDROSS (1963). The chemiluminescence of the related diaryl oxalate (**5**) is particularly significant because it came to commercial fruition in the form of chemical light sources (see Section 2.5.1).

4

5

Radical-initiated autoxidation of alkyl-substituted aromatic hydrocarbons in solution was first shown by VASIL'EV and BELYAKOV (1967). The termination of peroxy radicals is responsible for the formation of the electronically excited product (Russell mechanism). In the presence of efficient fluorophors, e.g., 9,10-dibromoanthracene, the chemiluminescence is strongly enhanced.

Although dioxetanes (**6**) were postulated in the early 1900 s, KOPECKY and MUMFORD succeeded in isolating the first stable deriva-

tive, trimethyl-1,2-dioxetane, only in 1969. α-Peroxylactones (**7**) (1,2-dioxetanones), which in the mid-1960 s were proposed as intermediates in firefly bioluminescence, were synthesized for the first time by ADAM and LIU (1972). Dioxetane chemiluminescence is an active field of research [179] with promising medical applications [180].

6 **7**

Chemically induced electron exchange chemiluminescence (CIEEL) was discovered by SCHUSTER (1977), who showed that diphenoyl peroxide (**8**) in the presence of easily oxidized electron donors leads to efficient chemiluminescence. The process is general and applies to a wide range of other cyclic peroxides, e.g., phthaloyl peroxide (**9**) and the peroxalate (**10**). Particularly significant is the fact that the α-peroxylactones (**7**) exhibitCIEEL, which implies that some forms of bioluminescence, such as that of the firefly, follow this mechanism.

8 **9** **10**

The demonstration by CILENTO et al. (1977) that horse radish peroxidase-catalyzed autoxidation of enolizable carbonyl compounds leads efficiently to chemiluminescence opened up new pathways in the production of electronic excitation in cells. The biological consequences of this novel form of generation of excited state are far-reaching [180], because although the cell may use them beneficially to generate bioluminescence, the high-energy intermediates involved may induce cellular damage.

2.3. Mechanisms of Light Emission

With few exceptions, processes involving autoxidation or peroxides or both are predominant in chemi- and bioluminescence; for further details, see [176–179].

Three distinct mechanisms of light emission are known: direct, enhanced (energy transfer), and chemically induced (electron exchange) [179]. The chemiluminescent decomposition of α-peroxylactones (**7**) is given here as an example. For this case, in the direct mechanism an excited carbonyl derivative ($R_2C{=}O*$) is the emitting species (Eq. 1).

(1)

Firefly bioluminescence is an example of such direct emission [176].

In the enhanced mechanism, the first step is also the generation of $R_2C{=}O*$, but in the presence of an efficient fluorophor, e.g., 9,10-dibromoanthracene (DBA), the emitting species is the electronically excited DBA$*$ (Eq. 2). The DBA$*$ results from energy transfer between $R_2C{=}O*$, the energy donor, and DBA, the energy acceptor.

(2)

For efficient enhanced chemiluminescence, the fluorophor must be chosen such that the energy transfer is exothermic and its emission quantum yield high. By judicious choice of the fluorophor, the wavelength of the emitted light can be manipulated in this indirect form of chemiluminescence. In bioluminescence, the luminescent jelly fish *Aequorea* falls into this category [176], for which a photoprotein acts as fluorophor.

In the chemically induced mechanism (CIEEL) in addition to the chemiluminescent compound e.g., the α-peroxylactone (**7**), a fluorophor is necessary that is also a good electron donor, e.g., rubrene (Rub). As shown in Equation 3, the emitting species is electronically excited rubrene (Rub$*$).

The Rub is energized by electron exchange, involving chemically induced electron transfer between **7** and rubrene to form a radical ion pair. Subsequent decarboxylation of the radical anion affords the ketyl radical, which transfers an electron back to the radical cation, generating Rub∗. The emitted light in this CIEEL process is characteristically that of Rub. This type of light emission mechanism operates in the firefly and the chemical light source Cyalume.

2.4. Efficiency of Light Emission

Consider the sequence of steps outlined in Equation 4 for a generalized chemiluminescent (bioluminescent) process.

(a) chemical reaction	R	$\rightarrow$ I	Φ_{chem}
(b) excitation	I	$\rightarrow$ P*	Φ_{exc}
(c) energy transfer	P* + F	$\rightarrow$ P + F*	Φ_{et}
(d) transmission	P*(or F*)	$\rightarrow$ P(or F) + light	Φ_{em}

(4)

In step (4 a) a chemical reaction (e.g., autoxidation, thermolysis, or electron exchange) transforms reactant R into a high-energy intermediate I that is capable of generating the necessary excited states for chemi- or bioluminescence with an efficiency Φ_{chem}. In the excitation step (4 b) the electronically excited product P∗ is formed, for which the efficiency is given by Φ_{exc}. In the presence of an appropriate fluorophor F, the electronically excited fluorophor F∗ is obtained by energy transfer (4 c), characterized by the efficiency Φ_{et}. Finally, in step (4 d) the observed emission occurs from P∗ or from F∗, depending on whether direct or enhanced (indirect) chemiluminescence (bioluminescence) applies, with an efficiency Φ_{em}. The quantum yield of chemiluminescence (bioluminescence) $\Phi_{CL(BL)}$, is given by the product of the efficiencies for the individual steps involved. Thus for direct emission

$$\Phi_{CL(BL)} = \Phi_{chem}\Phi_{exc}\Phi_{em} \tag{5}$$

and for enhanced emission

$$\Phi_{Cl(BL)} = \Phi_{chem}\Phi_{exc}\Phi_{et}\Phi_{em}\,. \tag{6}$$

Of these efficiencies, all but Φ_{exc} can in principle be determined experimentally by modern analytical methods. For example, conventional photometry is usually used to measure Φ_{CL} or Φ_{BL} [176, 177].

If the high-energy intermediate I, e.g., a dioxetane, can be isolated and purified, Φ_{chem} is necessarily unity. Otherwise Φ_{chem} must be independently determined by analytical techniques such as chromatography and/or spectroscopy. However, for very labile and short-lived transients, this is difficult, and large uncertainties in Φ_{CL} and Φ_{BL} can arise from this difficulty alone.

The Φ_{em} term is a characteristic photophysical property for P∗ (direct emission) or F∗ (enhanced emission), corresponding either to the fluorescence or phosphorescence efficiencies of the emitting species. In favorable cases these may be reported in the literature, but hardly ever under exactly the same conditions as required for the chemi- or bioluminescent experiment. When not available, standard fluorescence or phos-phorescence measurements must be performed to determine Φ_{em}.

The energy transfer efficiency Φ_{et} (only for the enhanced emission) is determined by means of Stern – Volmer kinetics, by determining the quantum yields Φ_{CL} or Φ_{BL} as a function of fluor-ophor concentration. The intercept of a double-reciprocal plot of Φ_{CL} or Φ_{BL} versus [F] provides these efficiencies at infinite fluorophor concentration, the conditions for 100 % efficient energy transfer, i.e., $\Phi_{et} = 1.0$. For further details see [179].

Once all efficiencies are experimentally determined, the excitation parameter Φ_{exc} can be calculated according to Equation 5 (direct emission) or Equation 6 (enhanced emission). This parameter is an inherent and characteristic property of a chemi- or bioluminescent species and takes values in the range 0 to 1 [176–179].

The firefly is one of the most efficient bioluminescent systems with $\Phi_{exc} = 0.88$. On the other hand, bacterial bioluminescence has $\Phi_{exc} = 0.1$. Among the chemical systems, the perhydrolysis of diaryl oxalates (enhanced chemiluminescence) is one of the most efficient, with $\Phi_{exc} \leq 0.3$. For comparison, the direct chemiluminescence arising from luminol autoxidation has $\Phi_{exc} = 0.01$. Nevertheless, even such inefficient chemiluminescent systems are profitably exploited in applied work.

2.5. Uses

Uses of bioluminescence include illumination, decoration, pleasure, decoy, bate, military purposes, scientific applications, medical use, and industrial needs.

Since almost all chemi- and bioluminescent systems involve autoxidation, one of the earliest analytical applications concerned monitoring the amount of oxygen in biological media or the enzymatic production of hydrogen peroxide by peroxidases. However, when it was realized that ATP is essential to release the bioluminescence of the firefly, a new era of scientific, medical and industrial activity and interest in biological and chemical light was initiated.

Applications in the gaseous, liquid, and solid states are known; details are given in [176–179].

2.5.1. Light Sources

One of the evident commercializations of chemiluminescence is its use for illumination. Cyalume lightsticks, pioneered by American Cyanamid, stand out. The diaryl oxalate/hydrogen peroxide/fluorophor chemiluminescent system is the source for this chemical light. Its color can be adjusted from blue to red, depending on the fluorophor used. Electron exchange chemiluminescence is usually the mechanism responsible for light production.

Because neither ignition nor electrical current is envolved in chemiluminescence, it is ideal for safety lights. Consequently it is used more and more as emergency lighting in camping, boating, and diving. It is also finding more frequent use as marking light for handicapped people, children, joggers, and animals. Chemical light sources are also used as bait in fishing and hunting and decoration in night performances. Besides the diaryl oxalate/hydrogen peroxide/fluorophor system, tetrakis(dimethylamino) ethylene – oxygen chemiluminescence also finds occasional use.

2.5.2. Chemical Analysis

Enormous progress has been made in the use of chemi- and bioluminescence in the qualitative and quantitative analysis of chemical and biological substances in clinical chemistry, food science, agricultural chemistry, soil science, cell physiology, microbiology, marine biology, medicine, veterinary medicine, and others. Particularly decisive for this development is the enormous sensitivity of modern photometric equipment. Thus, as few as 1000 photons can be detected with current single photon counters, which under optimal conditions correspond to a lower concentration limit of ca. 10^{-21} M that can be monitored in practical situations. The advantages of these analytical tools are high sensitivity, broad scope, high reproducibility, enormous selectivity, small sample size, low cost, convenience, speed of analysis (in optimal cases fractions of a second), low hazard, and minimal toxicity. Luminol, lucigenin, and diaryl oxalates are the most extensively used chemiluminescent systems. Of the many bioluminescent systems, the firefly, lumibacteria, and luminous jelly fish (*Aequorea* and *Obelia*) are used most frequently.

Nearly all chemiluminescent systems require molecular oxygen or hydrogen peroxide and a suitable catalyst. Thus, luminol requires cooxidants such as heme, peroxidase, peroxydisulfate, ferricyanide, or redox-active transition metals. Lucigenin requires transition metal ions as cooxidants, while for diaryl oxalates, alkaline conditions and an appropriate fluorophor are essential, e.g., polycyclic aromatic hydrocarbons (derivatives of pyrene, anthracene, tetracene, xanthenes, porphines).

For the bioluminescent systems, specific cofactors are needed in addition to the appropriate enzymes (luciferases or dioxygenases), and the luminescent substrate or luciferin. In the case of firefly bioluminescence, ATP serves this purpose, while bacterial bioluminescence depends on NADH (nicotinamide adenosine dinucleotide, reduced form) and FMN (flavin mononucleotide, oxidized form). *Aequorea* and *Obelia* bioluminescence utilizes Ca^{2+} ions and photoproteins

(aequorin and obelin), since their mechanism of light emission involves energy transfer. These cofactors in the chemi- and bioluminescent systems allow for selectivity and differentiation in chemical and biological analyses.

Since all the above-mentioned light-emitting systems require molecular oxygen or hydrogen peroxide, it is not surprising that these chemicals figured among the first in chemi- or bioluminescent assays. Luminol and lumibacteria permit the detection of ca. 10^{-13} M concentrations of molecular oxygen in aqueous solution. Such sensitivity allows the measurement of oxygen production at the cellular level, and numerous oxygen electrodes have been developed for this purpose. The concentrations of hydrogen peroxide that can be monitored by these luminescent probes are as low as 10^{-9} M. Hypohalites and chlorine gas also serve as oxidants and can therefore be analyzed by these luminescent methods.

Since metal ions serve an important role as cooxidants in luminol and lucigenin chemiluminescence, analytical techniques have been developed to determine low levels (parts per billion) of metal ions. These include, with the exception of Cd(II), Hg(I), T(IV), V(V), Zn(II), Zr(IV), essentially all redox-active transition metal ions. Some of the more common ones are: Ag(I), As(III), Bi(III), Co(II), Cr(II), Cu(II), Fe(II), Ir(IV), Mn(II), Mo(V), Ni(II), Os(IV, V), Pb(II), Pt(II), Ru(III, IV), Tl(III), and V(IV).

A specific analytical method for detecting and quantitating Ca^{2+} ions is the use of the photoproteins aequorin or obelin. This has enabled studies of the role of intercellular Ca^{2+} ions, allowing investigations of the nature of electrical and chemical stimuli in biological processes. Since the jelly fish photoproteins are also ultrasensitive to Sr^{2+} ions, a potential application is the detection of traces of radioactive strontium in nuclear fallout.

The chemiluminescence of luminol has also been used for inorganic anions. The scope is more limited, but common examples include CN^-, SCN^-, OBr^-, S^{2-}, $S_2O_3^{2-}$, and SO_3^{2-}. For this purpose redox titrations are employed, allowing detection levels of the order of parts per billion.

Light-monitoring analyses are useful in the qualitative and quantitative analysis of organic compounds, especially those of biochemical interest. Both chemiluminescent and bioluminescent systems are used for this purpose. Either the assay exploits the fact that bio- and chemiluminescence usually involve autoxidation reactions or that specific cofactors (e.g., H_2O_2, Ca^{2+}, ATP) are necessary. The combination of these two features offers broad scope and also selectivity in chemical and biological analysis.

Luminescent assays exist for alcohols (ethanol), polyhydroxy compounds (glycerol, mannitol, sorbitol, inositol), and sugars (glucose). Their ability to release hydrogen peroxide on autoxidation and detecting the light emission stimulated by the hydrogen peroxide form the chemical basis of this analysis. Also acids, e.g., ascorbic acid, uric acid, and amino acids (thyroxine), have been employed. The latter inhibit the luminol chemiluminescence and are analyzed in that way. Chemiluminescent assays have been reported for esters, including glycerides, lactates, malates, pyruvates, and phosphates. Long-chain aldehydes are monitored by bacterial bioluminescence, since they are required as luciferins for the light emission.

Fluorescent polycyclic aromatic hydrocarbons, e.g., anthracenes, pyrenes, tetracenes, and heteroaromatic compounds, are conveniently analyzed by electron-exchange chemiluminescence with diaryl oxalates. A bioluminescence assay also exists for TNT, which can be detected at concentrations as low as 10^{-18} M by means of an elaborate bacterial assay.

Bio- and chemiluminescent analyses have been reported for a wide range of steroids (testosterone, pregnanediol, androsterone, cortisol, estradiol), some antibiotics (tetracyclin), leukemia tumor drugs (methotrexate), and sedatives (barbiturates, cocaine, heroin). Organophosphorus nerve gases and insecticides have also successfully been analyzed.

Some of the relevant biomolecules include numerous vitamins (B_{12}, biotin, ascorbate, and

folate); however, the most significant are the nucleotides ATP, c AMP, FAD, FMN, c GMP, and NADH. Adenosine triphosphate is the essential component of the firefly bioluminescent system. It is one of the most sensitive luminescent assays, allowing the detection of as little as 10^{-17} mol ATP. Since a single bacterium possesses only ca. 10^{-18} mol of ATP, the firefly luciferin–luciferase assay permits detection of ca. 10 bacteria per milliliter of medium.

The nucleotides NADH and FMN are important in bacterial bioluminescence. When employed together with proteins, particularly enzymes, an analytical tool of wide scope is available for biotechnological and biomedical purposes. By means of firefly and bacterial bioluminescence, compounds ranging from the simple tripeptide glutathione to complex proteins such as insulin, albumin, immunoglobin, hemoglobin, hematin, myoglobin, have been assayed. Prominent applications concern enzymes such as oxidases, dioxygenases, peroxidases, catalases, dehydrogenases, kinases, hydroxylases, and phospholipases.

2.5.3. Biotechnology

The fact that ATP can be conveniently monitored by firefly bioluminescence, allowing the detection of trace quantities (ca. 10^{-17} mol per mL medium), constitutes the basis of most biotechnological applications. Thus, the detection of harmful bacteria in industry, e.g., foods (*Salmonella*), beverages, crops, soils, sediments, textiles, waste waters, and fresh water, engage this ATP assay based on the firefly luciferin–luciferase system. Such ultrasensitive detection methods allow rigorous control of environmental pollution.

Another application concerns the use of bacteria for the removal of specific pollutants in waste water recycling. A major problem is to recognize at an early stage when the viability of the specially cultured bacteria is endangered. By means of genetic engineering, the bacteria are equipped with genes for luminescence, permitting their function to be monitored. Diminished light-emission indicates that poisons are reducing the bacterial population, and immediate corrective measures can be taken.

The aging (autoxidation) of foods can be easily assessed by using lumibacteria to assay the resulting peroxidic products. This assay also allows the quality and efficiency of antioxidants for foods to be tested.

Promising opportunities concern monitoring biologically relevent processes by using proteins equipped with chemi- and bioluminescent agents. They should constitute efficient tools in biomass analysis, microbial assays, and germ warefare. Much progress along these lines is anticipated in the future.

2.5.4. Medicine

The quantitative analysis of ATP with the firefly luciferase – luciferin system also has medical applications. Thus, bacterial infections that increase the amount of ATP in the blood and urine can be detected very efficiently, conveniently, and at low cost. In fact, this ATP analysis was one of the earliest applications of bioluminescence.

The involvement of Ca^{2+} in heart disease and multiple sclerosis can be monitored with the jelly fish photoproteins aequorin and obelin.

A field of intensive activity in medicine concerns phagocytosis, in which macrophages employ intensive autoxidative activity to clean up infected cells, increasing (decreasing) the oxygen metabolites in the living system [177]. Disorders such as rheumatoid arthritis, lung diseases, muscular dystrophy, cystic fibrosis, ischaemic and myocardial infarction, carcinogenesis, diabetes, foetal and neonatal abnormalities, immune-based diseases, and others can be detected and monitored at an early stage.

The most important advances have been made in immunoassays. The high sensitivity rivals that of radioassays, but the problems involved with working with radioactive isotopes are avoided, and the cost is considerably lower.

A distinction is made between luminescent immunoassay (LIA), luminescent enzyme immunoassay (LEIA), luminescent enzyme multiplied immunoassay technique (LEMIT), and luminescent cofactor immunoassay (LCIA) [177].

Luminol and diaryl oxalate chemiluminescence and luciferin and bacterial bioluminescence are frequently used. Hormonal diseases, genetic disorders, endocrine problems, and nu-

merous other medical challenges have already been successfully dealt with.

1. Introduction

Magnesium [*7439-95-4*], Mg, A_r 24.3050 [58], is a silvery white metal; it has a valence of two, and its configuration is $1s^2, 2s^2, 2p^6, 3s^2$. The crystal structure is hexagonal close packed; lattice constants at 20 °C are $a = 0.32$ nm, $c = 0.52$ nm. The element has an atomic number of 12 and belongs to Group 2 of the periodic table. It occurs as three isotopes: ^{24}Mg (78.70 %), ^{25}Mg (10.13 %), and ^{26}Mg (11.17 %) [59].

History. Magnesium was recognized as an element by Black in 1755. Magnesium metal was first isolated by Davy in 1808, via electrolysis of anhydrous magnesium chloride with a mercury cathode. Bussy extracted the metal in 1828 by reducing fused magnesium chloride with potassium vapor. In 1833 Faraday electrolyzed dehydrated liquid magnesium chloride to form liquid magnesium and chlorine gas. The first industrial production of magnesium by electrolysis of molten carnallite began in 1886 in Hemelingen (Germany).

In 1940 L. M. Pidgeon pioneered the first industrial metallothermic magnesium extraction plant in Canada; it was based on early German patents in which dolomite was reduced with ferrosilicon under vacuum [1].

2. Properties

Physical properties of magnesium follow (for further data, see [2], [58], [59]):

Mechanical properties of magnesium are listed in Table 1. Its dynamic modulus of elasticity is 45 GPa, and its static modulus of elasticity 43 GPa. Pure magnesium is not used for commercial structural applications although the metal has a high damping capacity and is easily machined and formed into shapes by casting or hot forming processes [3].

Chemical Properties. Pure magnesium has a high resistance to corrosion because its galvanic activity is low. Contamination with heavy metals (usually copper, iron, and nickel), chlorides, and oxide or nitride inclusions combined with exposure to chloride-containing solutions on untreated surfaces, strongly promote corrosion due to enhanced galvanic activity. The metal is readily dissolved by most organic and inorganic acids. A protective layer of water-insoluble magnesium hydroxide is formed when magnesium is exposed to moist air or clean water at room temperature. Magnesium is resistant to alkali metal hydroxide solutions, hydrofluoric acid, fluorine, and fluorine compounds (including ammonium hydrogen difluoride) due to the formation of protective hydroxide and fluoride films.

The ability of magnesium to form stable protective oxide, chromate, phosphate, sulfate, and fluoride films is employed commercially in protective coating systems used as primers for paints or as final coatings (→ Magnesium Alloys, Chap. 5.3.). The behavior of magnesium towards various chemicals is listed in [8].

Magnesium burns in air with an intense white flame. The ignition temperature is 645 °C in dry air but decreases with increasing moisture content [5]. The rate of oxidation in moist air at different temperatures is illustrated in Figure 1 [7]. Burning magnesium reacts violently with water. Magnesium fires are extinguished with dry salts or fluxes (see Chap. 10). Magnesium reacts with gaseous chlorine to form $MgCl_2$ and with nitrogen at ca. 500 °C to form Mg_3N_2.

Figure 1. Rate of oxidation of magnesium in moist air [23]

3. Raw Materials [9], [10]

Magnesium is the eighth most abundant element in the earth's crust (average magnesium content, 2.1 %). Magnesium does not occur in nature in elemental form but in the form of compounds in seawater, minerals, brines, and rocks. The element is enriched in ultrabasic rocks.

The prime raw material sources for magnesium extraction are the minerals dolomite [*16389-88-1*] ($CaCO_3 \cdot MgCO_3$), magnesite [*12440-90-3*] ($MgCO_3$), and brucite [*1317-43-7*] ($Mg(OH)_2$); magnesium-rich salts such as carnallite [*1318-27-0*] ($MgCl_2 \cdot KCl \cdot 6\,H_2O$), kieserite [*14567-64-7*]

Magnesium-rich brines are obtained as byproducts from potash production or from surfacial or underground brine deposits. Analyses of some dolomites, magnesites, and brines used for magnesium extraction are given in Tables 2 and 3, respectively.

Magnesium silicates such as olivine [*1317-71-1*] ($MgFe(SiO_4)_2$), and forsterite [*15118-03-3*] (Mg_2SiO_4) have not been used so far for magnesium extraction. However, a new process has been developed by Noranda for leaching of magnesium from serpentinized material in rejects from asbestos production (asbestos tailings) [60].

Total world production of magnesium in 1999 was ca. 400 000 t, of which 54 % came from dolomite, 29 % from salt or brine deposits, 12 % from magnesite, and 5 % from seawater.

4. Production

Magnesium is produced commercially by electrolysis of magnesium chloride in chloride melts and by metallothermic reduction of magnesium oxide with silicon and/or aluminum. All extraction processes are followed by refining and casting.

4.1. Extraction by Electrolysis

The extraction of magnesium by electrolysis consists of two steps: (1) preparation of the magnesium chloride cell feed and (2) electrolysis.

4.1.1. Preparation of Magnesium Chloride Cell Feed

Cell feeds in industrial use are dehydrated $MgCl_2$ (s) or $MgCl_2$ (l); dehydrated carnallite $MgCl_2 \cdot KCl$ (s); and partially dehydrated $MgCl_2 \cdot 2\,H_2O$ (s). Most cell feeds contain 3 – 8 % alkali metal chlorides and minor impurities of C, SiO_2, MgO, SO_4^{2-}, B, and heavy-metal compounds. Alkalimetal chlorides accumulate in the electrolytic cell as major constituents of the electrolyte. Metallic and nonmetallic impurities are undesirable because they adversely affect the cell performance and the corrosion resistance of the magnesium produced.

Figure 2. Flow sheet for production of magnesium via chlorination of magnesia (Norsk Hydro)

The use of pure dehydrated magnesium chloride allows coproduction of highly concentrated chlorine gas and electrolysis at high current efficiencies. Dehydrated carnallite (which contains only 50 % $MgCl_2$) leads to accumulation of significant tonnages of potassium-rich electrolyte in the electrolysis. A water content corresponding to $MgCl_2 \cdot 2\,H_2O$ results in high consumption of anode carbon, formation of sludge, and higher power consumption in the cells.

The two main routes to the production of dehydrated magnesium chloride cell feed are: (1) chlorination of magnesia [*1309-48-4*] (MgO) or magnesite [*12440-90-3*] ($MgCO_3$) in the presence of carbon or carbon monoxide and (2) dehydration of aqueous magnesium chloride solutions (brines) or hydrous carnallite ($MgCl_2 \cdot KCl \cdot 6\,H_2O$).

Figure 3. The IG chlorinator
a) Refractory material; b) Charge; c) Carbon resistors; d) Steel mantel; e) Carbon electrodes; f) Door for slag removal

4.1.1.1. Chlorination of Magnesia and Magnesite

IG Farben Process (see Fig. 2). The principal process used industrially to chlorinate magnesia is the IG Farben process in operation at Norsk Hydro's Porsgrunn plant in Norway until 2002. In this process, caustic magnesium oxide (lightly burned), produced from seawater and calcined dolomite (→ Magnesium Compounds, Chap. 4.2.2.), is mixed with char (low-ash coke from lignite) and magnesium chloride brine on a rotating disk to form pellets with a diameter of 5 – 10 mm. Hydrated magnesium oxide and magnesium oxychlorides act as binders. After drying, pellets containing ca. 50 % magnesium

oxide, 15 – 20 % magnesium chloride, 15 – 20 % water, 10 % carbon, and a balance of alkali metal chlorides are conveyed to the chlorinators (Fig. 3).

The lower third of the brick-lined cylindrical shaft furnace is filled with carbon blocks (c) that act as resistors and are heated by carbon electrodes (e). Chlorine produced during subsequent electrolysis of magnesium chloride is introduced in the resistor-filled zone. The charge (b) resting on the resistor bed reacts with chlorine at 1000 –1200 °C. The reaction mechanism is complex and involves several side reactions. The main reactions are:

$$2\,MgO + C + 2\,Cl_2 \longrightarrow 2\,MgCl_2 + CO_2$$

$$Cl_2 + C + H_2O \longrightarrow 2\,HCl + CO$$

$$MgO + 2\,HCl \longrightarrow MgCl_2 + H_2O$$

Molten magnesium chloride is collected in the bottom of the furnace from where it is tapped and transported to the electrolytic cells in sealed containers.

Off-gases at 100 – 200 °C containing air, CO, CO_2, traces of HCl, Cl_2, SO_2, H_2S, and chlorinated hydrocarbons are scrubbed, and the remaining contaminants are incinerated before release to the stack. The wash water is filtered and chemically treated in several stages before release to the sewer. Slag rich in magnesium silicate may be formed due to the presence of silica in the magnesia and must be removed from the furnace at intervals.

The magnesium yield is ca. 90 %, and the carbon consumption is 0.4 t per tonne of magnesium. Magnesium chloride solution added to the pelletization stage compensates for chlorine losses. The anhydrous $MgCl_2$ product typically contains less than 0.1 % MgO, 0.1 % C, 0.1 % SiO_2, and 20 ppm B. Each chlorinator has an equivalent annual magnesium production capacity of ca. 2000 t.

In the electrolysis-based magnesium plants in China, similar chlorinators are used, charged with magnesite and coke.

The MPLC process was developed by MPLC [20] for the chlorination of raw magnesite with the use of carbon monoxide gas (CO). In the late 1980s MagCan built a plant in Alberta, Canada, based on this process. The main reactor was brought into production, but other operational problems were experienced. The costs related to modifications and optimization were significant. These factors, combined with a soft market, led to the plant's closure in 1991.

The main features of the process are: Natural magnesite in lump form is charged at intervals to a reactor of the same general description as the IG shaft furnace (Fig. 3), but taller. Chlorine from the electrolysis is mixed with fresh makeup chlorine and carbon monoxide from a gas generator and fed into the lower section of the reactor, where it reacts with preheated magnesite resting on a bed of carbon resistors. The main reactions are:

$$MgCO_3\,(s) + CO\,(g) + Cl_2\,(g) \longrightarrow MgCl_2\,(l) + 2\,CO_2\,(g)$$

$$CO_2\,(g) + O_2\,(g) + 3\,C\,(s) \longrightarrow 4\,CO\,(g)$$

During the reaction, the evolution of CO_2 from the calcination maintains an open passage for chlorine and carbon monoxide to penetrate the lumps, while magnesium chloride simultaneously drains from the surface [19].

The process is in thermal balance at 1000 °C which is also the temperature in the reaction zone. Off-gases leaving the top of the reactor at 150 – 350 °C contain primarily carbon dioxide and small amounts of carbon monoxide, hydrogen chloride, and unconverted chlorine. Molten magnesium chloride is tapped from the reactors at 800 °C.

4.1.1.2. Dehydration of Aqueous Magnesium Chloride Solutions

Brines with a high content of magnesium chloride may be derived from various sources: From solution mining of salt deposits, e.g., bischofite ($MgCl_2 \cdot 6\,H_2O$); as a byproduct from the potassium industry; or produced by dissolving or leaching magnesium-bearing minerals in hydrochloric acid (magnesite in the Norsk Hydro process, asbestos tailings in the Magnola process, precipitated magnesium hydroxide in the Dow Chemical process). Naturally occuring dilute brines are concentrated by solar evaporation (Magcorp process). Unwanted impurities in the brines (e.g., Fe, Ni, SO_4^{2-}, B, Br_2) are removed prior to dehydration.

Norsk Hydro Process (see Fig. 4). The Norsk Hydro dehydration process was developed to produce anhydrous magnesium chloride in the Porsgrunn plant from brines with 33 % $MgCl_2$, a byproduct from the German potash industry. Brine-based magnesium production in Porsgrunn was shut down in 1991 due to increasing brine costs.

Figure 4. Flow sheet for production of magnesium via dehydration of magnesium chloride brine (Norsk Hydro)

In the Norsk Hydro magnesium plant in Bécancour, Québec, Canada, started up in 1989, $MgCl_2$ brine is produced by dissolving magnesite in hydrochloric acid. Impurities such as heavy metals are removed by precipitation and filtration [103], [104]. Purified brine is concentrated by evaporation to ca. 50 % magnesium chloride before prilling. The granulometry of the prills is kept within close tolerances, and their shape is controlled to optimize the subsequent dehydration step in fluidized beds, employing hot air at 150 – 180 °C and finally hydrogen chloride gas at 300 – 400 °C [21]. Water and magnesium chloride dust in off-gases from the hydrogen chloride dehydration step are absorbed in concentrated magnesium chloride solution [105]. Essentially dry hydrogen chloride gas is heated and returned to the hydrogen chloride dehydration step. Magnesium chloride prills containing < 0.1 % magnesium oxide are transported pneumatically to the electrolysis cells. The chlorine gas produced in the electrolysis is recycled by reaction with hydrogen in HCl synthesis furnaces to produce the hydrochloric acid used in the dissolving of magnesite. Energy is recovered from the HCl synthesis by raising steam [116].

Figure 5. Flow sheet for production of magnesium via dehydration of brine (Magcorp)

Magcorp Process (see Fig. 5). The magnesium plant at the Great Salt Lake, Utah, was started up in 1972 and is now owned and operated by Magnesium Corporation of America (Magcorp). Great Salt Lake water is concentrated in solar evaporation ponds to precipitate potassium chloride, sodium chloride, and some carnallite ($MgCl_2 \cdot KCl \cdot 6\,H_2O$). The resulting

crude brine contains 7.5 % Mg, 4 % SO_4^{2-}, and < 1 % K and Na, and is desulfated with calcium chloride solution generated in the process. The boron content is decreased from 500 to 3 ppm by liquid extraction with kerosene. The brine is preheated before spray drying by direct contact with hot off-gases from the spray dryers. Each spray dryer is connected to a turbine fired with natural gas. Exhaust gases enter the top of the spray dryers at 515 °C. The energy efficiency of this system is ca. 80 %.

The spray-dried powder contains ca. 4 % water and 4 % magnesium oxide. It is melted in an electrically heated, brick-lined melt cell and treated with carbon and chlorine gas to lower the content of magnesium oxide, water, bromine, sulfate, aluminum, and heavy metals. In a second reactor vessel, impurities are further reduced with chlorine gas in the presence of carbon at 830 °C to an average magnesium oxide level of 0.05 %. Iron(III) chloride acts as a catalyst in these reactions.

Off-gases containing chlorine, hydrogen chloride, sulfur dioxide, magnesium chloride dust, and chlorinated hydrocarbons are scrubbed with milk of lime to form the calcium chloride used in the desulfatation stage. The molten magnesium chloride product is transported to the electrolytic cells in trucks and contains 95 % $MgCl_2$, < 0.1 % MgO, and 0.01 % SO_4^{2-}, the balance being alkali metal chlorides. The process is a net producer of chlorine [22].

Dow Chemical Process (see Fig. 6). Dow Chemical started magnesium production in Freeport, Texas, in 1941. Dow was for a long period of time the largest magnesium producer in the world. However, the Freeport magnesium operation was closed down in 1998. The process has been licensed to a prospective magnesium producer in Australia [61].

In the Dow process, hydrous magnesium chloride ($MgCl_2 \cdot 2\,H_2O$) is used as cell feed. Magnesium hydroxide slurry precipitated from seawater with sodium hydroxide or calcined dolomite is dewatered on rotary filters to 8 – 12 wt % magnesium, dispersed in magnesium chloride solution, and neutralized with hydrogen chloride. Sufficient sulfuric acid is added to precipitate excess calcium, which is then removed by filtration. Sulfate ions are adjusted by a proprietary process. The brine is further concentrated to 35 % magnesium chloride. The purified brine is fed to a dryer where it is concentrated further to 70 % magnesium chloride, which is a dry granular solid. Alternatively, the 35 % brine can be concentrated directly to 70 wt % solid particles in a spouting bed where the brine is sprayed on solidified particles in an airstream at 180 °C. Undersized particles are separated in cyclones and returned to the dryer.

Figure 6. Flow sheet for production of magnesium from seawater (Dow Chemical)

The hydrogen chloride used for neutralization of the magnesium hydroxide is partly recovered from the anode gases and partly added to the hydrogen chloride furnaces as makeup chlorine in various forms.

Magnola Process. Noranda Inc., Canada, has developed this process, which is implemented in the Magnola Metallurgy magnesium plant started up in Danville, Quebec, Canada, during 2000 – 2001 [60]. The raw material is asbestos tailings, i.e., mining residues from the asbestos industry, containing up to 24 % Mg in serpentine minerals. The raw material may typically contain 40 % MgO, 38 % SiO_2 and 5 % iron compounds. The tailings are first subjected to a magnetic separation step to remove most of

the iron. The material is then leached with concentrated hydrochloric acid (33 % HCl), and the brine produced is neutralized in two steps with controlled pH to avoid the formation of silica gel while precipitating other impurities. Leaching residues and precipitated impurities are removed by filtration; the resulting purified brine contains 27 % $MgCl_2$.

Figure 7. Flow sheet for production of magnesium via magnesium hexammoniate (QMC)

The brine is fed to a fluidized granulation and dryer bed, which produces free-flowing granules of hydrated magnesium chloride $MgCl_2 \cdot x\,H_2O$ with $x \approx 2$ and a content of ca. 2 % MgO. The final dehydration and chlorination are carried out in so-called super-chlorinators, in which the granules are melted in a bath of molten electrolyte recirculated from the electrolysis cells [62]. HCl gas is sparged into the super-chlorinators, reacts with MgO, and removes the water of hydration from the melt. The HCl gas is produced by reacting chlorine gas from the electrolysis with hydrogen in HCl synthesis furnaces, and the HCl-containing off-gas from the super-chlorinators is recycled as hydrochloric acid for leaching of the tailings.

QMC Process (see Fig. 7). Queensland Metals Corp. (QMC) of Queensland, Australia, has developed this process in cooperation with CSIRO of Australia, primarily for the exploitation of the huge cryptocrystalline magnesite deposits in Queensland (Kunwarara, Yaamba). This process is a further development of the Nalco process [18] [63].

Magnesite is dissolved in hydrochloric acid in two or more stages with controlled pH at each stage [64]. The resulting magnesium chloride brine is converted to anhydrous magnesium chloride cell feed for magnesium electrolysis by the following process steps [65]: The hydrous magnesium chloride brine is mixed with ethylene glycol to form an ethylene glycol magnesium chloride hydrate solution. This solution is subjected to distillation under vacuum to remove all or most of the water, resulting in a dehydrated magnesium chloride glycolate ($MgCl_2 \cdot 3\,HOCH_2CH_2OH$) dissolved in ethylene glycol. The dehydrated solution and anhydrous ammonia gas are introduced separately and simultaneously into a crystallizer containing ethylene glycol saturated with ammonia, whereby crystals of magnesium chloride hexammoniate ($MgCl_2 \cdot 6\,NH_3$) are precipitated. The hexammoniate precipitate is separated from the liquid phase and washed with methanol saturated with ammonia. Traces of methanol are removed by heating the crystals to a temperature of max. 120 °C. The hexammoniate crystals are then calcined in a fluidized bed at 400 °C or more to produce anhydrous magnesium chloride and release ammonia. The ammonia gas from the calciner is recycled to the crystallization stage, and the liquid streams from the crystallizer and the washings are processed to recover ethylene glycol, methanol, and ammonia for recycling. Salts other than $MgCl_2$ dissolved by the hydrochloric acid, e.g., $CaCl_2$, accumulate in the recycled ethylene glycol and can be removed by treat-

ment of the recycle stream. The hydrochloric acid for dissolving is produced by reacting chlorine from the magnesium electrolysis with hydrogen in HCl synthesis furnaces.

An alternative dissolving process has been proposed to avoid water in the dissolving steps by leaching magnesium from partially calcined magnesite with ammonium chloride dissolved in ethylene glycol and thereby reducing the energy consumption in the overall process [66].

4.1.1.3. Dehydration of Carnallite

Carnallite cell feed for magnesium production is used in the former Soviet Union (Russia, Ukraine, and Kazakhstan) and in Israel. Carnallite ($MgCl_2 \cdot KCl \cdot 6\,H_2O$) is obtained as a natural mineral, from solar evaporation of Dead Sea waters, or as a byproduct from the production of potassium chloride from complex salt deposits. Dehydration of carnallite is simpler than that of aqueous magnesium chloride because hydrolysis is weaker.

According to [23], impurities in the carnallite must not exceed the following levels: $CaSO_4$ 0.06 %, B 0.001 %, Fe 0.01 %, and SiO_2 0.01 %. The sodium chloride content may be 5 – 7 %.

Carnallite is dehydrated in two stages. The first stage is performed in a fluidized bed at 160 – 200 °C to give a water content of 3.7 – 4.8 %. The second stage, which yields molten dehydrated carnallite, is performed in a chlorinator at 700 – 750 °C. The chlorinator combines melting, chlorination, and settling – mixing in a single unit. The final product contains 49 – 51 % magnesium chloride and 0.6 – 1 % magnesium oxide. Efforts are being made to reduce the degree of hydrolysis during dehydration and to replace the chlorination stage by hydrogen chloride treatment in a fluidized bed. With carnallite as the raw material, about 4.5 t of excess electrolyte is produced as a byproduct per tonne of Mg; this byproduct with ca. 80 % KCl content is preferably used as a fertilizer.

4.1.2. Electrolysis [7]

Magnesium chloride is electrolyzed in a molten mixture with alkali metal chlorides at 660 – 800 °C, the operating window being limited on the low side by the freezing point of magnesium and on the high side by its rapidly increasing vapor pressure. The main electrochemical reaction is:

$$MgCl_2\,(l) \longrightarrow Mg\,(l) + Cl_2\,(g)$$

The electrolyte is contained in brick-lined vessels or unlined steel casings. For most electrolytes used, the magnesium metal collects on top of the electrolyte because of its lower density. Industrial electrolytic cells differ in electrode configuration, flow pattern of the electrolyte, and collection system for reaction products. Steel cathodes and graphite anodes are arranged vertically or at an angle. Electrodes may be monopolar, bipolar, or a combination of both, with interpolar gaps ranging from 3 to 12 cm and current densities from 2000 to 8000 A/m^2.

Electrolyte filled with chlorine gas adjacent to the anodes has a lower density than the bulk electrolyte, which results in circulation. The chlorine gas is separated from the circulating electrolyte, which then carries magnesium globules to the metal-collecting area. Salts in the cell feed of metals less noble than magnesium, e.g., alkali metal chlorides and calcium chloride, accumulate in the cell and have to be removed from time to time.

Alternative electrode materials have been the subject of research and development efforts, but not commercialized. A patent [36] covers inert anodes protected by a ceramic cover of doped and sintered Ti^{IV} and Ti^{III} compounds. Experiments have been carried out with CuAl bronze as an inert anode material [67]. Also anodes made of metal carbides, metal borides, metal nitrides, tantalum, tantalum oxides, and barium titanates have been tested [68]. Addition of H_2 to the anodes has been proposed so that the cells produce HCl rather than Cl_2 [69], [70]. Cathodes made of or coated with molybdenum have been proposed to avoid cathode wear [71].

Electrolysis of magnesium oxide dissolved in various chloride and fluoride electrolytes has been considered. Considerable work at the U.S. Bureau of Mines in the 1940s revealed the potential of and problems with the electrolysis of magnesium oxide [72]. This line of development has been pursued in several directions, with emphasis on fluorides [11], [12], rare

earth chloride or fluoride additions [73–76], and oxide conducting membranes [77]. Composite MgO – C anodes have been tested in fluoride, fluoride – chloride, and chloride electrolytes on a laboratory scale [13]. However, the solubility of magnesium oxide in all investigated electrolytes is low, and practical solutions for metal collection in industrial operation have not been found.

Electrolysis of magnesium chloride in aqueous solution liberates hydrogen, not magnesium, at the cathode. Attempts to electrolyze magnesium salts in organic solvents have not been successful.

4.1.2.1. Technical Data

The free energy and enthalpy of decomposition of $MgCl_2$ to Mg and Cl_2 at 1000 K are 482.7 and 596.7 kJ/mol, respectively. The corresponding decomposition potentials are 2.501 and 3.092 V, the former being the reversible decomposition potential and the latter the isothermal decomposition potential ($\Delta H/2F$). However, in a technical electrolyte where $MgCl_2$ is mixed with other alkaline earth metal chlorides and alkali metal chlorides, the reversible decomposition potential is higher due to the lower activity of $MgCl_2$. The activity varies from electrolyte to electrolyte. A typical $MgCl_2$ activity in a technical electrolyte is 0.02, yielding a reversible decomposition potential at 1000 K of 2.67 V. According to Faraday's law, 4.534×10^{-4} kg Mg is produced per A · h at a current efficiency of 1.

Theoretical energy consumption under thermoneutral conditions is 6.8 kW · h/kg Mg. In industrial cells, however, electrical energy consumption may range from 10 to 20 kW · h/kg. Correspondingly, 32 – 66 % of the energy input is lost as heat as a result of ohmic resistance in the electrodes and electrolyte, overvoltages on the electrodes and recombination of magnesium and chlorine. Heat generation is necessary to compensate for heat losses from the electrodes and the cell surface. Heat balances for cells are discussed in [7]. Current efficiencies normally range from 0.75 to 0.95. The main cause of reduced current efficiency is the recombination of dissolved chlorine and magnesium in the electrolyte.

The composition and main characteristics of electrolytes used in the electrolysis are listed in Table 4; they normally contain 8 – 20 wt % magnesium chloride. Other chlorides ($BaCl_2$ or LiCl) may be added to influence the density; lithium chloride also increases the conductivity of the melt. The density of the lithium – potassium chloride electrolyte is lower than that of liquid magnesium, permitting magnesium to collect at the bottom of the cell. The solubilities of magnesium and chlorine in commercial electrolytes are of the order of 0.005 wt % and 6×10^{-7} mol/cm^3, respectively. Solubilities increase with increasing temperature [24].

Comprehensive measurements of the characteristics of electrolyte compositions and the pure salts are reported in [25–31]. At 750 °C the standard decomposition voltages of the electrolyte components are: $MgCl_2$ 2.51 V, NaCl 3.22 V, KCl 3.27 V, LiCl 3.30 V, $CaCl_2$ 3.33 V, and $BaCl_2$ 3.40 V. Some sodium is always deposited into the magnesium metal phase, and the sodium content in the metal depends on the concentration of $MgCl_2$ and the cell design. With magnesium chloride contents below ca. 5 %, the current efficiency may be substantially reduced due to recombination of sodium and chlorine, which causes a temperature rise.

Impurities in the cell feed disturb cell performance by passivating the cathode surface and hindering the coalescence of metal globules or their free rise to the surface. Upper limits for impurities in cell feed, in parts per million, have been indicated in [7], [32], as shown in Table 5.

Table 5. Upper permissible limits for some impurities in cell feed (in ppm)

Electrolyte	Composition, wt %	*mp*, °C	Properties at 700 °C			
			Density, kg/m^3	Conductivity, S/m	Viscosity, mPa·s	Surface tension, mN/m
Potassium	5 – 12 $MgCl_2$ 70 – 78 KCl 12 – 18 NaCl	650	1600	183	1.35	104
Sodium – potassium	10 $MgCl_2$ 50 NaCl 40 KCl	625	1625	200	1.58	108
Sodium – calcium	8 – 16 $MgCl_2$ 30 – 40 $CaCl_2$ 35 – 45 NaCl 0 – 10 KCl	575	1780	200	2.22	110
Lithium – potassium	10 $MgCl_2$ 70 LiCl 20 KCl	550	1500	420	1.20	
Lithium – sodium	10 $MgCl_2$ 70 LiCl 20 NaCl	560	1521	488		
Sodium – barium	10 $MgCl_2$ 20 $BaCl_2$ 50 NaCl 20 KCl	686	1800	217	1.70	110
Magnesium		650	1580			

the electrolyte are reported to counteract these undesired effects.

Magnesium chloride and magnesium react with oxygen in air or with oxygen-containing compounds in the cell feed and the brick lining to form magnesium oxide, which has a low solubility in the melt. The oxide can form a layer on the cathode surface, resulting in higher electrical resistance. Magnesium oxide with entrapped electrolyte and magnesium globules form a sludge at the bottom of the cell which must be removed at intervals. The amount of sludge generated is significantly lower in sealed as opposed to open cell designs.

Theoretically, 2.917 t of chlorine is produced per tonne of magnesium. The chlorine yield from commercial cells varies, depending on design, but can be as high as 2.9 t of chlorine per tonne of magnesium at concentrations above 98 wt %. Commercial cells operating with yields of 2.7 – 2.85 t of chlorine are reported [79],[80]. The chlorine gas from the cells contains small amounts of air, dust from the electrolyte components, and minor amounts of chlorinated hydrocarbons, which require efficient systems for collection and destruction. Electrolytic magnesium contains typically $\geq$ 99.8 wt % magnesium.

4.1.2.2. Electrolytic Cells

IG Cell. The cell concept developed by IG Farben Industrie in Germany in the 1930s was used extensively in the Soviet Union, Norway, and the United States, but has now been replaced by new developments. Figure 8 illustrates the electrode configuration and the circulation of the electrolyte [32].

The brick-lined cell is divided into compartments by semisubmerged refractory partition walls (c). Cooled graphite anode plates (a) are installed and tightly sealed in the refractory cover of the cell. The semi walls on each side of the anodes separate the magnesium metal and the chlorine gas. Steel cathodes (b) are installed in the cathode compartments from above or through

the sidewalls. The metal is collected from each of several cathode compartments and chlorine from each anode compartment. Extensive cathode chamber ventilation causes oxygen and water in the ventilation gases to react with metal and electrolyte to form sludge. The current efficiency is typically 0.80 – 0.85, and the amperage is in the range 60 – 120 kA. The chlorine concentration may reach 90 – 95 wt % and is limited by air leaks through the semi walls. Anode consumption is 15 – 20 kg per tonne of magnesium. The power consumption per kilogram of magnesium is 16 – 18 kW·h when operated on molten magnesium chloride. For further details of the IG cell, see [33].
